It is well known that the activity of a gland varies directly in proportion to its blood supply. In blood, the liver is richer than any other organ save the lungs. In pregnancy and in chlorosis this is distinctly lessened. In like manner, as shown by Ranke, in violent muscular exertions such as are produced by tetanus, the blood flow to the liver is so lessened that its bile output practically ceases.

It is an easy and a natural step from these facts to the assumption that in the laborer so much blood is used by the muscles that not a sufficiency remains for the liver. Indeed, it may well be possible, according to Hartmann, that, particularly in patients whose biliary system is congenitally abnormal, there may not alone be an absence of flow of bile but actually a *negative* pressure. This not alone tends to aspirate the colon or other bacilli from the duodenum—despite the Valvula Heisteri, but to create by the anemia a *locus minoris resistentiæ* where germs might grow apace. So, often between the twentieth and thirtieth years the corner-stone, so to speak, is laid—but the growth is slow.

Symptoms may not develop for ten or fifteen years, but the *disease* is there. These conclusions of Hartmann are of great interest and his tables will reward the most patient study.

## A NEW BLOOD PARASITE.

In addition to the routine activities of a health department, the Montana State Board of Health has undertaken and apparently carried out to a successful issue a very commendable piece of work in the investigation of a peculiar disease known to them locally as spotted fever.

In the Bitter Root Valley there has existed for some time a disease which has been responsible for many deaths and which has created more or less alarm in the minds of the residents of that valley, the cause of which has been attributed to various factors, particularly the water, the mineral and the general conditions of the soil, and by many thought to be due to the snow of the Bitter Root Mountains. This disease, known in Montana as "spotted fever," "black fever," or "blue disease," has been recognized as a clinical entity by the physicians of the region for fifteen to twenty years, the first case having occurred as far back as 1873, from which time to the present over 200 cases of the severe type have occurred, 70 to 80 per cent. of which have proved to be fatal. During the spring of 1902, 18 cases of the disease were observed, 15 of which died.

The disease seems to be confined to the eastern foothills of the Bitter Root Mountains, arranged along the top of which runs the Montana-Idaho State line, and few if any cases have been known to originate in Montana outside of this territory.

The investigation was taken up by Doctors Louis B. Wilson and Wm. Chowning, both connected with the University of Minnesota, and State Board of Health. They entered upon their investigations May 16, 1902, and after a most thorough search found in the red blood cells of the patients suffering from the disease, a new parasite closely resembling the *Pyrosoma bigeminum*, the cause of Texas fever, yet differing from that organism in being larger, and in its larger forms exhibiting active ameboid movements. The absence of pigment from the organism of spotted fever separates it, the authors think, from that of the malarial group and places it in close alliance with the parasites found to be the etiological factors in Texas fever. The investigators, however, prefer to make a more extended investigation of the parasite before determining its exact zoological relationships.

An extremely interesting feature of the observations is shown in a possible relationship of the tick which is found on the gray gopher, *Spermophilus columbianus*, as the chief agent in the spreading of this disease. It is well recognized that this class of insect is responsible for the spreading of Texas fever in cattle and man and the occurrence of an analogous species of tick in the gopher widens still further our outlook on the

relationship of animal parasites to the spread of disease. Furthermore, the authors show that the parasite is found in the red blood cells of the gopher and it is probable that this animal serves as the host of the new hematozoan.

While there are many points to be cleared up before final conclusions can be drawn on all of the side issues relating to "spotted fever," the authors are to be commended for their extremely painstaking piece of work, the credit of which should be ascribed in large part to the enlightened policy of the newly created Montana State Board of Health.

## ECHOES AND NEWS.

### NEW YORK.

**Dr. Alfred Meyer.**—The President of the American Congress on Tuberculosis, to be held in Washington, D. C., April 4, 5 and 6, 1905, announces Dr. Alfred Meyer, of New York City, consulting physician to the Bedford Sanitarium for Consumptives, chairman of a committee in charge of the section on sanitarium treatment of tuberculosis. It is probable that the climatic and other methods of treatment will be comprised under the work of this committee.

**Work of Lying-in Hospital.**—In the month of July the new Lying-in Hospital, at the corner of Seventeenth street and Second avenue, has had 572 applicants for treatment, of whom 135 were admitted and cared for in the hospital wards. The number of children born in the hospital during July was 110. For the same period in the outdoor department, 303 applicants have applied for assistance in their own homes, and 208 patients have been treated in confinement. The number of medical visits made was 880.

**New Bellevue Hospital Now a Probability.**—President of the Board of Trustees of Bellevue Hospital J. W. Brannan on last Monday announced that certain difficulties which had been encountered in connection with the acquisition of the block between Twenty-eighth and Twenty-ninth streets, running down to the East River, had been disposed of, and that the way was now clear for the Department of Charities to acquire the land. The difficulties centered particularly about the dock which the city owns at the foot of Twenty-eighth street, and the dumping ground for the Street Cleaning Department at Twenty-ninth street. It was desirable that these places should continue to be maintained, yet their continued presence meant that the elaborate plans for the new hospital could not be carried out in their entirety. Repeated consultations were had between the Superintendent and Dock Commissioner Hawkes and Street Cleaning Commissioner Woodbury in an effort to find a way out of the difficulty. At last, after close scrutiny of the official maps of the city, it was found that the city and dock rights at the foot of Twenty-ninth street and the dumping ground for the Street Cleaning Department could be moved up a block, to Thirtieth street. With this discovery the solution of the difficulty has been found. A short while ago the Board of Aldermen authorized condemnation proceedings begun to acquire the block in Twenty-eighth and Twenty-ninth streets. The principal building at present on it is the power house of the United Electric Light and Power Company. The company offered to sell to the city their rights in the property for $1,460,000. This was considered too high a price, and the condemnation proceedings were then authorized. The acquisition of this property will remove a nuisance which has long been a source of annoyance to the hospital authorities—the tall smokestack attached to the power house, which frequently emitted big clouds of black smoke, permeating the hospital buildings. President Brannan said last Monday that in all probability work would be begun on the new buildings for the hospital about October. It is planned to start building at the northern end of the site, the Twenty-ninth street end. As soon as one building is ready for occupancy, one of the old ones will be torn down, and so on until all the old buildings have been removed. Mr. Brannan said that the cost of land to be acquired and the sums to be spent to put it into condition for building will amount to about $2,000,000. The site will comprise the lots from Twenty-sixth to Twenty-ninth street and from First avenue clear to the river.

**Hudson Water Favored.**—It was stated at the Water Department last Monday that the preliminary report of the special commission on additional water supply, which was appointed by the Mayor early in the year, will be made public about September 1. Commissioner Monroe said some time ago that the report would be ready about July 1, and the delay is explained on the ground that the Commissioners were asked by Mayor Low to make an investigation of the Jerome Park reservoir, and were obliged to let the water investigation rest for a while. It was stated, also that the report which is expected in September will contain more detail than it was originally proposed to incorporate in the preliminary report. Just what the commission will recommend is not definitely known, but from the best information obtainable it is said that its members have agreed that the Hudson River above Poughkeepsie is the most promising and permanent source of supply for the entire city. The commission has examined all possible sources, but it is understood that the main objection to most of them is that while they might meet the present demands, the growth of the city would, in a few years, render it necessary to again seek additional sources. The main objection to the Hudson River source is said to be expense. To distribute water in Brooklyn, large mains would have to be constructed under the East River, and, it is claimed by many engineers, the water would be so brackish that it would have to be put through an elaborate process of purification before it could be safely consumed.

**A Plea for the Dogs.**—Apropos of our discussion on Hydrophobia, in the Original Articles in the NEWS this week the following letter to the New York *Times* is deemed pertinent. We reproduce the article in full:

To the Editor of The New York *Times:*

DOG ORDINANCE SIGNED.

Mayor Low yesterday signed the dog-muzzling ordinance.

Tut-tut! Likewise avaunt!

As a loyal Columbia man, I had almost taken it for granted that, although the Board of Aldermen would of course put their feet in it, our worthy ex-President could be depended upon to spare me, in the "dog-days," by a wise veto, the bother of buckling on my armor and shivering a lance for the reputation of this town for mercy and justice toward our brute friends.

A time or two in the past I have published in your

columns over the pseudonym of "Quaestor" views upon matters and things which have been so happy as to meet with your subsequent editorial approval. Let me humbly hope for a like fate to-day; after which I will resume my palmleaf fan and be able to look my dog in the eye without fancying therein a look of mute contempt and reproach.

The present agitation, worked up by one of our newspapers during the "silly season," in absence of a better occupation, and helped by misjudged action by the County Medical Association, and resulting in an official scare about dogs, reminds me of nothing so keenly as the spectacle of a lady with skirts closely wrapped about her person standing upon a chair in deadly fear of a mouse upon the floor. That lady is New York to-day.

Of course, rabies does occur occasionally, but chiefly in winter time most rarely when the weather is hottest. The statistics of the Pasteur Laboratory of Paris, quoted by Dr. Ruffer of that laboratory in a report to the British Medical Association (see N. Y. Med. Record, Sept. 28, 1889, p. 357 et seq.), show that the lowest number of cases of mad dog bite occurs in August, the highest number in February.

It cannot be too strongly affirmed that in hot weather, for one genuine case of rabies there are many of supposed rabies, which are due to nothing save the wearing of a muzzle during the heat. Because of this torture (unless the muzzling is a mere farce and utterly useless to prevent biting) the mouth is at least partially closed. In summer this often compels sunstroke, in consequence of which the dog is apt to act queerly—or even to have a fit; whereupon the poor beast is chased and finally shot. The incident is closed by a record in the newspapers of one more case of hydrophobia "in our midst."

Dogs vary in temperament as do human beings. Those of a nervous and excitable nature may temporarily go crazy, as a man of like temperament might become delirious from heatstroke.

May I, with apologies, right here deliver a two-minute lecture upon dog physiology? It is guaranteed to do nobody any harm.

Dogs have no sweat glands. Upon the most sultry day their skin will be found dry. But they must of course lose water to keep cool. This they do from the tongue, which drips steadily, but possibly even more is lost by means of panting. The inhaled air is comparatively cool and dry. The exhaled is hot and saturated with moisture. By these means alone can they accomplish what we do by aid of our sweat glands chiefly. Among human beings it is always the person not perspiring who, if anybody, is in jeopardy of heat stroke. The mechanism whereby a dog in need of cooling his blood makes some 200 or more times per minute the respiratory motion called panting, demands for its performance as nature intended, a wide-opened mouth. With a mouth in which the oscillatory motion of the tongue is restrained even in the least by muzzling, the resultant fatigue, within a short time, is pitiful to witness. It is pure cruelty. Most wickedness begins in ignorance, and this is no exception.

If we must have muzzling, it should be, as a matter of logic, in midwinter since, as I have shown, rabies is commonest then. However, restraint at the end of a strap or chain would seem the proper solution of the problem. I, too, approve of restraint —to this degree, and throughout the year. Also, I am regretfully compelled to agree with the strongly expressed opinion of the late Col. Waring, speaking in his capacity as guardian of the city's cleanliness, namely, "town is no place for a dog."

It is a matter of more than usual interest just now to inquire whether the common expression "the dog days," meaning the heated term, may not in part have helped to fix in the popular mind the mistake regarding the danger from hydrophobia being greatest during that period. Of course, the reasonably well-read know that "the dog days" have no such meaning nor peril. They are forty days, figured twenty before and twenty after the first morning that Sirius, the Dog star, becomes visible before sunrise.

They also have been called "Canicular Days," but Shakespeare uses the expression "Dog Days" for them. When first named and observed, the reckoning was from July 3 to Aug. 11, but the procession of the equinoxes changes this forward a day in each seventy years, and the dog days now run from July 25 to Sept. 3.

The writer of this letter devoutly wishes that the public could be induced to stun by blows, and not kill with bullets, dogs that apparently have gone mad. Afflicted with genuine rabies, the poor animal is certain to die, and quickly. If instead it is heatstroke, abundance of cold water and possibly blood letting may save its life.

If it recovers, think of the relief from mental anguish of those who may have been bitten by the crazed animal, and who now know that they are in no jeopardy of madness: have no need to undergo the Pasteur treatment. Because of the present foolish plan of killing at sight every dog in a fit in summer time, an unspeakable amount of anxiety and dread, most of it wholly needless, is caused among those bitten.

Indeed, there is actually a disease called Lyssophobia (Lyssa is one of the names for rabies), which at times, among the highly strung and hysterical, is capable of killing. It is death from pure fright, with symptoms imagined by the victim to be those he ought to have—such as barking like a dog, etc.

To return to our incubus, the present statute. What are we to do with it? Enforce it? Never! I have too much confidence in the common sense of the citizens of this city, even those in high places, to believe it of them. I appeal from Philip drunk to Philip sober of thought. In an address before us of the Nineteenth Century Club last winter Recorder Goff, in speaking of a wholly different matter, said that there is certainly no lack of laws upon our statute books, as affecting the City of New York. On the contrary, quoth he, there are enough laws existent and unenforced to start a respectable law library!

In view of the facts in this case, as presented herein, am I wrong in feeling that the best way out of a rather shameful situation will be to add just one more—namely, this newest ordinance, to the long list alluded to by our distinguished Recorder? Let it be honored in the breach.

Of course it is admitted that under ordinary circumstances the best way to treat an objectionable law is to enforce it rigidly. Those suffering injustice will be loud in their protests, and a sense of justice will lead to its repeal. But in the present instance the victims cannot ask for fair play.

If it were not asking too much of poor human nature—for it needs the rare quality called moral courage to admit a blunder—I would suggest that the Aldermen should at once repeal this ordinance, substituting therefor one commanding a leading cord, strap, or chain, and omitting all reference to that instrument of torture, the muzzle.

Quaestor.

**The Insane at Bellevue Pavilion.**—The Evening Post very sanely says: "Whatever the insane pavilion at Bellevue may have been in days not so long gone, when many grim and ghastly tales of abuse of patients were made public, there is no evidence on these fair mornings to warrant a belief that it is anything but an efficiently conducted hospital ward. Since the new board of trustees of Bellevue and Allied Hospitals went into office, they have effected many reforms; none of them, perhaps, shows more distinctly when contrasted with former conditions than the present methods of caring for the insane while awaiting discharge or commitment to an institution. Unfortunately, the penny papers have fostered popular superstition about the insane pavilion among the very people who largely fill its beds. They regard it as a place of horrors, and delay putting their friends and kinspeople under treatment, usually, until the police interfere. A visit quickly belies the ignorant and commonly held misconception of the place. The two long wards are specklessly clean and bright, the sunlight coming through the iron-grilled windows, giving the long rooms a particularly cheery appearance. The ward for females upstairs is even brighter, being lighted by skylights as well as windows. Several cages filled with singing canary birds, the big rocking chairs, and the tables, gave the ward the air of a big living room. The sleeping rooms are on either side of the broad hallway extending the length of the building. Despite their cheerful surroundings and the presence of the rosy-cheeked, white-capped nurses going briskly about the morning's routine, the women patients sat gloomily apart from one another.

**In the Male Ward at Bellevue Pavilion.**—In the men's ward there was a more social air. All of the patients, wearing pink pajamas, were in groups chatting softly. One man was earnestly reading the classified advertisements in a newspaper held upside down. He was arrested for writing threatening letters to consuls and port officials reciting alleged grievances. He came by his delusions honestly enough in the "fire hole" of a South American steamer. He was a stoker, and the work, combined with the effects of a spell of fever in Santos, addled the none too deep contents of his brain pan. Except for the woman who cried, all of the patients might have been convalescents from any ordinary illness. The insane pavilion rarely ever comes to public notice, save through the medium of some tragedy or scandal of mismanagement, and account is not taken of the many weeks when nothing untoward happens. Previous to the present administration the patients were in the care of physicians with little experience in the treatment of the insane. During their absence the members of the regular house staff of the hospital performed these duties in addition to their own. This arrangement was so obviously unwise that the new trustees named Dr. F. Packer resident physician and gave him two assistants, Dr. M. S. Gregory and Dr. D. C. MacClymont. All of them had had previous experience in asylum work. A system of hospital treatment has been adopted, so that all cases are given the benefit of the same service as in a general hospital for the care and treatment of the insane. The use of mechanical restraint has been abolished except in cases where it is absolutely essential to prevent injury to the patients or their nurses, and it is only applied on the order of the medical officers. The use of the belt, cuffs and waist straps has been discontinued. Where necessary, a restraining bed sheet and bandages are applied under the direction of the medical officers only. The use of sedatives as a restraint has been reduced to a minimum, and they are only given on the prescription of a medical officer. An increased number of patients have been furnished with employment about the wards and in the performance of other duties to the end of relieving the monotony of their detention. An improved system of case records has been adopted. A report of the physical and mental condition of each patient is recorded. These reports are supplemented by the daily notes of the nurses under the direction of the medical officers, and contain a complete record of all medicines prescribed.

**Changes in Nursing Service.**—In the male ward, the nursing service has also been materially changed. In place of pupil nurses, the patients are now in charge of trained asylum attendants who have been drawn to a large extent from the State hospitals. A carefully chosen woman head nurse has been placed in the ward with most happy effect upon the patients and the atmosphere of the ward. The number of attendants has also been increased, being now in the proportion of one attendant to three, or, at the most, four patients. The number of nurses in the female ward has also been increased. The work of the resident physicians has been greatly helped since the positions of examiners in lunacy were abolished. The employment of skilled alienists made this possible. The fact that the examiners in lunacy had their own private practice and were required to attend at the pavilion for but two hours in the afternoon of each week day, necessitated many delays in the examination of such cases as for any reason were not ready for treatment in those hours. About 2,500 men and women are brought to Bellevue yearly under the belief that they are insane, and the physicians are under the gravest responsibility lest some person who is not really deranged permanently be committed. Only recently a woman who tried to have her husband committed and who told a logical, circumstantial story of his alleged symptoms, was found on examination to be as mad as a hatter. Her husband was detained three days before it was determined that he was sane, and that it was his wife who needed restraint. Another woman who had her husband locked up because of his alleged insanity came to the hospital the following day and threatened to clear out the place unless "her man" was released. She had charged him with insanity in a fit of anger after a quarrel.

## PHILADELPHIA.

**Physicians Fined for Failing to Report Smallpox Cases.**—Two physicians have each been fined $5 and costs by Magistrate Cunningham for failing to report cases of smallpox to the Bureau of Health. One of the cases had been diagnosed as chickenpox.

**Quarantine Upheld by Court.**—Judge Davis, in Quarter Sessions Court, recently dismissed the writ of habeas corpus brought to gain the liberty of Norman R. Hyland and his family, who were declared to be starving to death after a week's smallpox quarantine at their home. The action of the Bureau of Health in denying Hyland, his wife and three children the means to obtain food was said to be due to the man's persistent refusal to have one of his children, suffering from smallpox, removed to the Municipal Hospital. The Bureau of Health justified its action by the fact that the city has a hospital for all such cases. The attorney for Hyland demanded that the man be allowed to work or that the city provide food for the family. After hearing the testimony of both sides, Judge Davis said the case narrowed down to the question as to whether the

Board of Health had a right to quarantine the house. This right was given, the Judge said, in an act of 1818. He declared that if the condition of the family was as stated it was unfortunate. "But," he continued, "if provision is to be made for families under quarantine in their homes, there would be danger of many families being under quarantine for 365 days of the year."

**Pasteurizing Plant in Operation.**—The pasteurizing plant donated by Nathan Straus, of New York, was put in operation August 5. Dr. A. R. Green from the plant in New York said that Philadelphians should be proud of their laboratory as it has larger quarters and is more completely equipped than any other in this country. Branch distributing stations are to be established in different sections of the city. Contributions to the amount of over $2,000 have already been made for the support of the enterprise. The milk will be given free on an order from a physician or recognized charity, but if the persons applying for it are in a position to pay they will be charged a nominal sum. For a six-ounce bottle or under the price will be one cent, for an eight-ounce bottle, two cents, for a sixteen-ounce bottle, three cents.

**Dr. Royer to Head Municipal Hospital.**—Dr. B. Franklin Royer has been selected by Director Martin to be head of the Municipal Hospital. Although a young man, Dr. Royer has had considerable hospital experience, having been chief resident physician at the Jefferson Hospital for the past seventeen months. He is about thirty-seven years old, and a native of this State. He was educated at the Mercersburg Academy, and entered Jefferson Medical College in 1895. He was graduated in 1899, receiving a gold medal and highest honors in obstetrics. He was immediately appointed a resident physician in the college, the first man to be appointed that year, and he served fourteen months before becoming chief resident physician. As chief resident physician, Dr. Royer will reside in the Municipal Hospital, and will give its affairs his undivided attention. Dr William M. Welch will, it is understood, be retained by the Board of Health in a responsible position, where his expert knowledge of contagious diseases will be utilized. It is thought that he can do especially valuable work in connection with the work of the health inspectors.

**The White Haven Sanatorium.**—In a recent article read at the Luzerne County Medical Society, Elwell Stockdale, Superintendent of the White Haven Sanatorium of the Free Hospital for Poor Consumptives, gave some very interesting points regarding the work of that institution. During the first winter their 18 patients slept in a dilapidated barn, the thermometer often below zero and no heat whatever in the building. In spite of these conditions the patients contracted no colds, pleurisy or pneumonia and never since have the results quite equaled those obtained during that period. This is a strong argument in favor of the tent theory for all winter, yet Stockdale would hardly advise anyone to try it. At present the Sanatorium has 100 beds with a large waiting list. All patients whose temperature permits are kept out of doors eight hours daily. On forced feeding every patient is compelled to take not less than four quarts of milk and six fresh raw eggs daily, and many take six quarts of milk and 12 eggs daily, a few even more. They believe that no patient who cannot take forced feeding has much chance of recovery. Breakfast is a light meal served at seven o'clock. At nine o'clock a lunch of milk and eggs is served, and at twelve o'clock dinner, which is the only heavy meal of the day. At four o'clock is given a lunch of milk and eggs and soda crackers, and at seven o'clock supper. The minimum, but not the maximum, quantity is limited. No patient with a temperature above 99½° F. is allowed to move about, and above 100° F. they go to bed. All patients rest in bed not less than ten hours. Some of the gains in weight are remarkable, one man gaining 23½ pounds in twenty-five days. The results are equaled nowhere else, either in this country or abroad. Stockdale says the secret of their success is their method of feeding, the careful individual attention given each patient, and the rigid rules to which all must adhere or leave. Spitting on the ground is made a cause for expulsion. The medication used is europhum in all cases, and varying tonics to aid digestion in most cases. Expectorants when the patient has a cold and creosote in all cases with mixed infection. Whisky is never given. For hemorrhages nitroglycerin is used, and as a precaution against them it is also given when there is an accentuation of the pulmonary second sound of the heart.

## CHICAGO.

**Mortality Statistics.**—Notwithstanding, or because of, the unusual character of the weather during the month just ended, the July death rate, 14.92 per thousand per annum, is more than 16 per cent. lower than the average of the ten previous Julys, which was 17.84. Three other years of the period, however, show lower July rates, namely, 1889, with a rate of 14.45; 1900, with a rate of 14.34, and last year, when the rate was 14.74.

**Better Treatment of Diphtheria by Antitoxin Among the Poor.**—Looking to the better safeguarding of the fund for the antitoxin treatment of diphtheria among those unable to pay for the remedy, arrangements have been perfected during the week whereby the Bureau of Charities will investigate all cases in which the Department furnishes antitoxin free on the claim of poverty. This will cause no delay in administration; the case will be treated first and investigated afterward.

**Typhoid in Chicago.**—There is no doubt that the inhabitants of Chicago attain a certain immunity in using the untreated lake water, and people who have been spending the summer away are more susceptible when they return to the city than if they had remained here. Nearly one-fifth of the typhoid cases are contracted away from the city. Many small towns and cities that are summer resorts along the shore of Lake Michigan and other neighboring lakes have imitated Chicago in their water supply and sewage disposal, except that, instead of the sewer and water intake being miles apart they are only a few hundred feet. There is some risk in omitting boiled water even when on a vacation.

**Milk Supply in Chicago.**—Publicity promotes purity of the milk supply. The publication of the names of delinquent dealers causes increased effort to obtain good milk. The Milk Bureau holds the dealer responsible; it cannot go back of him to the farmer. One result is that 769 samples of milk and cream were tested in the laboratory during the week—one-third of them being brought in by the dealers themselves. Only 2.8 per cent. of these were found below grade, and only 4.8 per cent. below grade from all sources. The improvement is remarkable.

## GENERAL.

**Transmission of Syphilis as a Penal Offence.**—A man has been sentenced to five months' imprisonment in Munich for having knowingly infected a

woman with syphilis. The judgment was based on the ground that a serious injury had been inflicted on the complainant.

**Cancer in Hungary.**—The number of deaths from cancer in Hungary is about 8,000 annually. The Budapest Society of Medicine has appointed a committee to make an inquiry into the distribution and prevalence of the disease in the country. The committee, of which Dr. J. Döllinger is chairman, has issued a schedule of questions on the subject to all medical practitioners in Hungary.

**Rabies in Cats.**—Owing to the prevalence of rabies among the cats of Amberg, Bavaria, the authorities gave orders for a massacre, and not a single cat has survived.

**Mortality and Birth-rate of the World.**—According to a recent calculation, there are 68 deaths per second; 97,920 daily, or 35,740,800 yearly. Births occur at the rate of 70 per second; 100,800 daily, or 56,792,000 yearly.

**First French Antituberculosis Congress.**—This congress will meet in the grand amphitheater of the Faculty of Medicine in Paris, October 26 to 29, 1903.

**Smallpox in Jersey.**—There is a good deal of excitement in Hightstown, a small town near Trenton, because of the existence of smallpox within its limits and the lack of a head to its board of health. Dr. William L. Wilbur, a physician of the town, has been medical director of the board for a long time, but he has come to the conclusion that his private practice will not permit him to give his attention to public health matters and has resigned. Dr. Elmer J. Rogers was appointed to succeed Dr. Wilbur, but he has respectfully declined the honor, and Inspector August T. Skillman has handed in his resignation. Meanwhile, the smallpox has been gaining headway.

**Preacher a Health Officer.**—In an effort to secure a thoroughly clean town for Pottsville, Pa., the Board of Health last Monday elected the Rev. W. D. Williams, pastor of the Congregational Church, as the town's Health Officer. Mr. Williams will wear a policeman's star and uniform and will devote all of his time to the work.

**Chickenpox at Goat Island Naval Station.**—All anxiety over the health conditions at Goat Island naval station, where some disease like smallpox broke out, has passed away, and the place is reported free from any serious sickness, the temporary quarantine being raised. The disease has proved to be chickenpox.

**Another Myth Exploded.**—Some months ago a report reached England from Africa of the discovery of a plant, one of the basil family, which was obnoxious and even fatal to mosquitoes. The story excited interest and was fortified immediately, as all such tales are apt to be, by the testimony of persons who had known the plant all along, been intimately acquainted with its virtues, and had slept in happy immunity from mosquito attack in pestiferous tropical regions, after taking the simple precaution of hanging up a few basil leaves. It has now been proved beyond peradventure that all these yarns were the outcome of a profligate imagination or a malicious intent to deceive. The Governor of Sierra Leone has caused a number of exhaustive experiments to be made, the results of which prove conclusively that the mosquito cares no more for the basil plant than he does for the rights of the individual. If anything, he appears to have a mild sort of liking for it. Certainly he does not try to avoid its presence, or suffer any inconvenience from it. He will perch upon it unhesitatingly, sit upon it while meditating or completing his toilette, and eat his dinner under its shadow with the utmost nonchalance and satisfaction. Even when shut up in a bottle with it he lives for days or until he dies of hunger. But if you get a heap of basil leaves and set fire to them in your chamber, and keep on burning them until the smoke is so thick that you are reduced to a choice between instant flight or death by suffocation, any mosquito who is in your company will exhibit signs of discomfort. He may even swoon, but, so say the scientific experimenters, a little fresh air will speedily revive him. On the whole, the great basil mosquito cure must be relegated to the limbo of exploded frauds.

**Another Mosquito Peril.**—"The announcement of a new and infallible method of exterminating mosquitoes no longer excites more than a languid interest, this week's contribution to science being at least the third of its kind since the summer began," says the Evening Post. "The high note of the alto horn and the parasite with the terrible name of *Agamomermis culicis* have been invoked in vain. We now learn that mosquitoes will die if the X-ray is turned upon them. True beyond a doubt, but has the New Jersey physician reflected that mosquitoes are bound to die even when the ray is absent? The principle of post hoc, propter hoc has certainly been overworked in the discussion of the mosquito problem. The finding in holes and corners of the grisly carcasses of *Culex* and *Anopheles*, creatures whose whole life history may be comprised in a couple of weeks, does not prove the success of destructive agents. It is not to be doubted that, if a man should recite Gray's Elegy to a roomful of mosquitoes, some of his little foes would drop dead even before he reached 'Here rests his head upon the lap of earth.' It may be recalled that Alice, when she was being instructed in regard to the insects of Looking Glass Land, inquired what would happen if the bread and butter fly should fail to find its necessary 'weak tea with cream in it.' 'Then it would die, of course,' replied the gnat. 'But that must happen very often?' objected Alice. 'It always happens' was the gnat's answer. It will not do to forget in our experiments that the same thing is true of the mosquito."

**Missouri Valley Medical Society.**—The annual meeting of this society will be held in Omaha, September 14-15 (instead of 17, as previously announced). This change has been made at the request of the Committee on Arrangements. The Governors of the Knights of Aksarben have asked the members to be their guests on the evening of September 14. Invitations will be issued in due time to all members who signify their intention of being present at this meeting. Those desiring to contribute papers should send their titles to the secretary at once, in order to secure a place upon the program. A symposium on skin diseases will be a feature of the first day.

**The Psychology of Sleep.**—Under the caption of "The White Man's Intellectual Burden," the New York Sun contributes somewhat to the enlivening of the dog days, saying that "a gifted native of Ceylon, P. Arunachalam by name, has just discovered that a chief defect of us Westerners is a habit of wakefulness, or rather an inability to enter into the third order of sleep. As for the first and second orders, we are said to do fairly well. The first, it appears, is plain Western dreaming, or, in the finer language of the East, the discovery of 'an inner world full of intense life and emotion.' The second, unconsciousness of existence, followed, on waking, by the memory of 'a blissful haven of rest'; in plain English, sound sleep. The third is the 'sleep of light,'

otherwise 'luminous sleep,' and it is under the head of 'Luminous Sleep' that the Singhalese philosopher publishes his advice to the Western world. Now it is in this quality of somnolent luminosity that we are so deplorably backward; we can sleep and dream and we can sleep without dreaming and we can dream without sleeping, but what we cannot do is to 'lift the veil of sleep' and let in the light. But there is still hope for us; a few have acquired the habit and what we chiefly need is cultivation. For, as the author of this little pamphlet points out Tennyson, among others, achieved to the third estate by often repeating his own name, till—to quote his own words—'all at once, as it were out of the intensity of the consciousness of individuality, the individuality itself seemed to dissolve and fade into boundless being; and this not a confused state, but the clearest of the clearest, the surest of the surest; utterly beyond words, where death was an almost laughable impossibility . . . . etc. 'If the science of the spirit,' remarks the writer, commenting on this curious autobiographical confession of the poet's, 'were cultivated in Europe as it is in India . . . what heights might not so ripe a soul have scaled, what blessed vistas might he not have opened up to the West!'

"It is pleasant to find the Spectator, of London, considering this most abstruse and interesting suggestion with proper gravity in its physiological, psychological, moral, political and religious aspects, with due consideration of the duties of citizenship, of man in his relation to others and to himself; of the delicate distinction between credulity and faith, the broad distinction between religion and superstition, between civilized nations and savages, and finally between the white and the darker races. The discussion at last is reduced to the 'white man's burden,' which 'more truly even than the guidance of the empire,' is 'the feverish dominion of thought.' And this feverish dominion is, unhappily, disastrous to the estate of luminous sleep, which can coexist only with intellective oblivion. So much for the matter from a political and moral standpoint. What of it psychologically considered? 'In dreams,' says our Eastern teacher, 'we joy, sorrow or rage, as keenly as in the experience of the waking world.' 'Surely not,' answers his sober English critic. 'Tragedies which would madden were we awake, and visions of delights that transcend the beauties and marvels of the material world in their gorgeous pageantry, are all forgotten by breakfast.' True enough; but surely in our sleep we 'joy,' as our Singhalese friend would say, over the most trivial delights, and mourn excessively over sorrows hardly understandable in our waking hours. And what if these dream-joys and dream-sorrows be forgotten on the arrival of breakfast? It is but reasonable that we accept the unities here as we do in what we of the West are pleased to call real life. And though a dream be winged, as Alectryon informed his master on a notable occasion, yet sleep hedges it in and limits its flight. Our manifest duty, then, in order to achieve the Eastern idea of contentment, is to cultivate perpetual sleep—'the sublime and refined point of felicity called the possession of being well deceived.' Herodotus, the veracious, tells us of some nation or other that could nap six months together, and surely with a little practice one might learn to live through the rest of the year in the same comfortable state.

"There is, however, one manifest danger in this proposal. Should we all become perpetual sleepwalkers and frequenters of everlasting night, were there not some risk of a superfluity of dreamers and poets, an excess of that wisdom and omniscience that is at present the possession of a favored few? To vulgarize such knowledge would assuredly be to stir up that old debate, happily set at rest years ago in the Schools of the Decree; whether the bat flying through the translucidity of the horned gate might not, spylike, discover the morphean visions turning and unwinding in circular fashion the thread of the *rete admirabile* that wraps up the *attili* of ill-caulked brains."

**International Society of Ophthalmology.**—The International Congress of Ophthalmology, which was held in Utrecht in 1899, elected Switzerland as the country for its next meeting. The undersigned ophthalmologists have been constituted the organizing Committee of the Congress. They have elected as President, the eldest of their Swiss colleagues, Professor Dufour; Vice President, Professor Pflüger; Secretary and Treasurer, Professor Mellinger, and Professor Snellen, President of the last Congress, Honorary President. The President of the Swiss Confederation, Mr. Deucher, M.D., has accepted the position of honoray president of the Tenth Congress of Ophthalmology. The Swiss ophthalmolgists have enthusiastically received the news of the choice with which the Congress of Utrecht has honored their country. They have joined, and in their name an invitation is sent to take part in the coming congress. As the international congresses of ophthalmology meet every five years, the forthcoming congress will be held in 1904. Lucerne is the town in which the congress is to be held, the dates agreed upon being September 19, 20 and 21. These three days will be devoted to work, the mornings being reserved for *discussions*, the afternoons for practical *demonstrations*. Professor Snellen, Utrecht, President of the Ninth Congress; Dr. Barde, Geneva; Professor M. Dufour, Lausanne; Professor Haab, Zurich; Professor Pflüger, Bern; Dr. E. Landolt, Paris; Professor Mellinger, Bâle.

Colleagues desiring fuller information can obtain it from Walter H. Jessop, M.B., 73 Harley street, London; George Mackay, M.D., 20 Drumsheugh Gardens, Edinburgh; Henry R. Swanzy, M.B., 23 Merrionsquare, Dublin; Dr. De Schweinitz, 1401 Locust street, Philadelphia, U. S. A.; Dr. Coote, Quebec, Canada; Dr. Alfred Osborne, Alexandria, Egypt; who have been appointed correspondents for the United Kingdom and for the United States.

**Tuberculosis Sanatorium at Scranton, Pa.**—The sanatorium for consumptives was opened and received its first patient on August 3. The Society for the Prevention and Cure of Consumption will provide for 15 patients in tents during the summer and will erect permanent pavilions in the fall. It has purchased a 30-acre farm for this purpose, just outside the city limits, which has an elevation of 1,400 feet. Scranton is the first city to provide itself with such an institution by private subscription.

**Obituary.**—Dr. George W. Rolerfort, who was one of the most prominent negro physicians in New Jersey, and a Republican leader of considerable note in Essex County, died in Newark on last Thursday, of a stroke of apoplexy. He was stricken on Wednesday afternoon while in consultation with Dr. Livingston S. Hinckley, at the City Almshouse, of which Dr. Rolerfort was medical supervisor. Dr. Rolerfort had practiced in Newark for thirteen years and had acquired a large and lucrative practice and the respect of the medical fraternity. He was born at Lexington, Va., on June 20, 1860. He became a barber and earned enough to pay a tutor who en-

couraged him to go to Morgan College in Baltimore. During the summer he worked as a waiter at hotels and found at Water Gap a patron who paid for three years' course of study, which ended at the University of Pennsylvania.

Dr. Michael F. McGrath died of consumption at St. John's Church, Fishkill Landing, last Tuesday. His brother, the Rev. John J. McGrath, is pastor of the church. The deceased, who was thirty-five years old, was graduated from St. Francis Xavier College and the College of Physicians and Surgeons of New York.

Dr. Jannat Ernestine Hills died at the Willard State Hospital, Willard, N. Y., on July 11, 1903. She was a member of the medical staff of the hospital since November, 1895. She was born in Auburn, N. Y., in 1861, and was a graduate of the Woman's Medical College of Pennsylvania in 1893. After graduating she was for fourteen months an interne at the Sheltering Arms Hospital in Philadelphia, and afterward on the staff of the New York City Asylum for the Insane at Hart's Island. Dr. Hills was a member of the Seneca County Medical Association and of the New York State Medical Association.

## CORRESPONDENCE.

### OUR VIENNA LETTER.

(From Our Special Correspondent.)

Vienna, July 15.

WOMEN STUDENTS IN ZURICH—AUSTRIAN MEDICAL STUDENTS' CONGRESS—UNIVERSITY LIFE IN BUDAPEST—MEDICAL STUDENTS AND THE ARMY—GERMAN DERMATOLOGICAL ASSOCIATION.

The physicians of Zurich are greatly annoyed at a recently published novel written by Baroness Tlise Frapan. She records therein the observations and adventures of a young female medical student; by the way displays a terrible picture of the Zurich clinics, and especially of the repulsiveness of anatomy. The "Work," which is based rather on vulgar gossips than on scientific researches, or on the writer's own observations, was perused by the director of the Zurich clinics. Professor Krönlein, and he contributes in the *Neue Züriche Zeitung* a sharp and energetic critique, in which he challenges the author's statements on the part of the medical students. The critique was as sensational as the novel itself. The polemic is not yet finished. This was a good opportunity for the male students to assert their opposition to the female students, and the men have requested that women be excluded from the University. This was not complied with on the part of Profs. Krönlein and Eichhorst.

The Austrian medical students have recently held a congress at Vienna, wherein medico-social and educational questions were discussed. At the sessions the professors of the medical faculty of the Vienna University also were present, and at the close the minister of education gave an address. The new regulations relating to the examinations for the "Doctor" degree are especially interesting.

Prof. Benedict spoke of the history of Austrian medical education. He pointed out the merits of Thun, who constructed the system of examinations in the year of 1850. According to these rules there were no compulsory examinations to pass during the course of a school-year. This rational system was superseded by the era of severe superintendence and compulsory examinations were established. The result of this innovation has been that to-day every medical professor complains of *the low level of the examinations.* According to Benedict this system must be abandoned, because it leads to the neglect of the visiting of lectures, and it is a hot-bed for neurasthenia. He urges also the extension of the examining committee, in order to prevent one-sided questions. Billroth himself has said that 40 per cent. of the matter that one must learn for the examination's sake, is to be forgotten. Finally he holds that the half year—which a student must spend in military service—is quite superfluous.

Paul Libesny—a student—the leader of a previous action, which has led to very good results, demonstrated the deficiency of practical education. He urged that the material of country and district hospitals should be used for educational purposes.

Great attention was paid to the address of Prof. Schanta. He portrayed the miserable and insufficient location and staff of the clinics in striking colors. In providing for 3,000 labors (yearly) and an immense number of operations he has only two assistants. He disapproved of the habit of coaching, which is apt to spoil the ambition of the student, and moreover is very costly. It is to be hoped, that in the future, the assistants will receive such good salaries that they will not need to increase their incomes in such a manner.

The next speaker, also a medical student, similarly deprecated the coaching system, which besides other disadvantages induces the student to procure his practical knowledge outside the clinics. Dr. Sachs, a lecturer, on the contrary thinks that coaching, as such, is an important means of medical education.

The professional committee of the Budapest Royal Hungarian University elected at their session held on June 30th for dean Prof. Louis Thanhoffer, the renowned histologist; as secretary, Dr. Arpád de Bokay, professor of pharmacology; as notary, Michall Lenhossek, professor of anatomy; as librarian, Prof. Högyes, director of the Budapest Pasteur Institute.

The Minister of War has decreed that for native students who desire to enter the military service the sums of 480, 720 and 1,008 crowns a year shall be paid to them to aid them in the medical studies, during the last three years.

The eighth congress of the German Dermatological Society will be held at Sarajevo (Bosnia) from September 21st to 23d. The preparatory work will be done by a committee under the supervision of Dr. Lipot Glück, sanitary superintendent. The Bosnian government has not spared expense in encouraging a full meeting. It has provided free transportation to the Society from Bosna Brod (the limit of Bosnia) to Sarajevo and from thence an excursion train through Mostar to Ragusa on the Adriatic sea. Other excursions are also planned. The members of the congress and their families can be provided with full board during their stay in Bosnia and Herzegovina for very moderate amounts. Nominally they will be furnished in first-class hotels with everything except beverages for three days for fifty crowns. On the 19th of September the members of the congress will pay a visit to the urological and dermatological section of the Royal Hungarian Medical Society at Budapest.

Those intending to attend can get full information from Dr. Adolph Erdös in Sarajevo, Austria.

**Static Work and Respiratory Metabolism.**—That the consumption of oxygen and elimination of carbon dioxide are not always proportional to the amount of work performed by the body, is proved by the experiments of A. Bornstein and E. Poher (Pflüger's Arch., Vol. 95, Nos. 3-4). They find that in the case of static work, such as holding a weight out at arm's length, the metaholism does not increase proportionately to the weight carried, but at a greater rate.

## SOCIETY PROCEEDINGS.

### BRITISH MEDICAL ASSOCIATION.

*Seventy-first Annual Meeting, Held at Swansea, July 28, 29, 30 and 31, 1903.*

First Day.

**Presidential Address.—Evolution of Antiseptic Surgery.**—Dr. T. D. Griffiths delivered his address at the adjourned meeting of the evening after the Report of the council and the election of honorary members had been made. His address was in part as follows:*

"I have chosen for the subject of my address the evolution of antiseptic surgery and its influence on the progress and advancement of bacteriology and therapeutics, and the further practical application of our knowledge for the benefit of mankind. This subject is no doubt full of interest to us all, but it is far too long to be treated fully in the short space of time in which I have the honor of addressing you.

"In the first place, I must ask your indulgence to bear with me for a few minutes in reminding some of you of the practice of surgery, as we witnessed it in the best London hospitals some forty years ago. There are probably many of the younger members of the profession who have no conception of the condition and state of things in surgical practice even at so recent a period. During my student days in the latter end of the Fifties and early Sixties the large wards of our hospitals were filled with all sorts of cases indiscriminately—simple and compound fractures, suppurating joints, traumatic, senile, and hospital gangrene, erysipelas, septicemia, pyemia, and cases operated on for accidents and diseases, all of which were dressed by the same attendants. Each ward had its set of sponges for the purpose of dressing wounds, and these were used indiscriminately for the various cases under treatment. There was no such thing as absorbent cotton wool in those days, and great economy was observed in the use of lint. Linseed meal and charcoal poultices were frequently employed to sweeten and cleanse wounds and to encourage healthy suppuration. "Laudable pus" was a sign of good dressing and healthy action!

"The operating theater was often crowded with students from the dissecting room, and at the operations the great surgeon invarably wore, with evident pride, the same old black frock coat, buttoned up to the chin, which was kept ready for the occasion in the anteroom, and which was well stained and saturated with blood and matter. It is unnecessary to give a detailed account of the operations, but I may mention that the sponges which were used in the wards were also used at the operating table. Stout silk ligatures were employed to tie the blood vessels, and were left hanging out of the wound to be pulled at from day to day until they were separated by the process of suppuration.

"I well remember listening on one occasion to a clinical lecture on pyemia, which was delivered by the senior surgeon of a London hospital, who confessed to the students that the causation and vagaries of pyemia were inexplicable. To illustrate this remark, he reminded his class of a strong, healthy young man, who had been admitted to the hospital for a trifling accident, and who died shortly afterward of pyemia, while a middle-aged, drunken abandoned woman in the adjoining ward was convalescent after a serious operation.

"The dawn of antiseptic surgery was now not far off. Schwann's discovery of organic germs in the air led Pasteur to formulate a theory that fermentation is never excited except under the influence of microscopic organisms; and, further, that each particular organism sets up a peculiar species of fermentation. In 1861 Pasteur published the results of his researches on fermentation, and in 1863 he demonstrated that putrefaction was caused by minute organisms suspended in the air. Prior to this oxygen had been regarded as the agent which produced it.

"Lister, now aided by the result of Pasteur's researches, devoted his talent and energies to solving the problem of inflammation and its attendant suppuration in wounds. He was not long in arriving at the conclusion that it was due to decomposition—putrefaction—and he naturally evolved the idea that if decomposition of blood serum and destroyed tissue in wounds could be prevented, Nature would repair the parts much in the same way as she did in cases of simple fracture. He applied this principle to the treatment of wounds in his practice in the surgical wards at the Glasgow Infirmary, and afterward in Edinburgh, and used carbolic acid as his antiseptic agent.

"At the annual meeting of this Association held in Dublin in 1867, Lister communicated to the world the result of his investigation, and clearly enunciated the principles of antiseptic surgery, which we recognize and practise to-day. Naturally the practical application of these principles has since been gradually modified and improved. The use of the carbolic spray, which was at first a prominent feature of Lister's method, was gradually discontinued. It was found very inconvenient in practice, and not so necessary as it had been anticipated, and it was finally renounced by Lister himself in 1887. When the spray was given up greater attention was paid to the purity of the atmosphere in the hospital ward, and more especially in the operating theater, and of the instruments and dressings. Then, by a natural transition, attention was turned to the possibility of asepticism, with the view of discarding antiseptics at operations, and for the dressing of wounds.

"After some experience, not a few argued that the acme of success in surgery could be attained by the proper use of aseptic means. There is no doubt a great amount of truth in this, but not to the extent claimed by the advocates of asepticism. It must be admitted that the purest air which we can obtain in the operating theater contains micro-organisms, and some of these must alight on the surface of exposed wounds. Fortunately, there is far less danger of septic action being set up by micro-organisms floating in the air than by those which are conveyed to the wound by a foreign substance. The reason of this is probably that the pathogenic micro-organisms suspended in the air are less numerous, and, as a rule, less active than those which rest on solid or liquid substances. When no antiseptic lotion or swabs are used the aerial micro-organisms settling in the wound are left to the digestive cells and phagocytes to be disposed of. In ordinary circumstances and with proper aseptic precautions they are able to do so; but it cannot be denied that this delegation of trust to the cells, coupled with the possibility of imperfect sterilization of the skin and materials used at the operation, involves greater risk of disasters (such as are not unknown to some of us) than when antiseptic means are also used. We must be careful that the pendulum does not swing too far to the aseptic side. It is at all times a difficult matter to guard the surgeon's work effectually by means of sterilization against every possible access of pathogenic micro-organisms. Why should one trust to asepticism alone when the position can be made impregnable by the assistance of antiseptics, which are practically harmless to the healing process? It is therefore evident that the acme of safety is secured in operative surgery by the judicious application of the two principles advocated and practised by Lister.

* From advance sheets of the British Medical Journal, by courtesy of the Editors.

"The architect has been very rightly called into service to further the practical application of Listerism. This is especially to be noticed in the construction of modern hospitals, and in the addition of new operating theaters to old institutions. They are invaluable in surgical work.

"Some thirty-six years ago the mortality from major operations in the London hospitals was about 33 per cent. This high mortality, after major operations, is now reduced to about 3 per cent., and, after minor operations, practically to nil, as the outcome of Lister's antiseptic surgery.

**Nursing Institutions and Surgical Homes.**—"We are now doing, with the aid of public charity, all that science up to date can do to help the poor. Let us now consider for a moment what has been done, what is being done, and what should be done to meet the requirements of the middle classes for medical and surgical aid in time of need. Their own homes, or perhaps lodgings are often unsuitable for operative surgery, or for serious medical cases requiring skilful nursing. There are, it is true, many surgical homes in our large towns which are, with very few exceptions, private ventures for profit, many unworthy of recommendation.

**Bacteriology and Immunity.**—"The brilliant discoveries of Pasteur and the evolution of antiseptic surgery by Lister gave a great impetus to the study of bacteriology, with the result that new and unexpected discoveries were made as to the part played by bacteria in nature. We now find that these micro-organisms have a definite and important place in the scheme of nature. They are distinctly separated by gradation from both the vegetable and animal kingdom. They form a kingdom of their own which we may term the 'bacterial kingdom.' Their very existence appears to be antagonistic to both animal and vegetable life. Their object in nature is evidently one of destruction—the breaking up of complex molecules of animal and vegetable substances into simpler combinations. They are Nature's scavengers, and undoubtedly they are the causal agents of all the communicable diseases to which flesh, and not human flesh alone, is heir.

"The varieties of bacteria, differing in size, form, action, character, and power for good or evil, are almost endless.

"The bacteria with which we are familiar measure from $1\mu$ to $5\mu = {}^1/_{25000}$ to ${}^1/_{5000}$ in. If each bacterium measured ${}^1/_{10000}$ in. in length and ${}^1/_{25000}$ in. in breadth it would take 250,000,000 of these micro-organisms to cover 1 sq. in. of glass. These micro-organisms grow with great rapidity—a bacterium may reach maturity and divide or split into two in twenty or thirty minutes. If it is divided into two every half-hour it would produce a colony of over 16,000,000 in twelve hours. It has been shown in the laboratory that the growth and rapidity of production and the character of bacteria depend upon their surroundings, and that their virulence may be attenuated or increased according to circumstances. It is therefore evident that the law of evolution and involution of the animal and vegetable kingdoms applies also to bacteria. Supposing that the evolution of a new species of plant—say an annual—takes 336 years, then if the law is equally applicable to micro-organisms, a bacterium under favorable circumstances would take only one week to run through 336 generations, provided it took only thirty minutes to reach maturity and division, and so a new species might be thus rapidly evolved.

"I wish also to remind you, for the purpose of my argument, of the important fact that a bacterium may have two states or stages of existence. One is the active or vegetative stage, and the other the spore or resting stage. In the latter state, which may be compared to that of a hard nut or seed, it may remain dormant for a long time until the surroundings favor its development into the active state. This, as I shall show, has an important bearing on the treatment and etiology of specific diseases.

"Pasteur's and Davain's discoveries led up to Koch's investigation. Davain discovered bacteria in the blood of animals suffering from anthrax in 1863, thus confirming the observations made by Pollender in 1849. Koch repeated the experiments and finally established in 1876 the causal relationship of bacteria and disease. Tuberculous disease had been proved by Villemin to be inoculable, and in some countries it had long been believed to be infectious, but it remained to Koch to demonstrate, in 1882, that tuberculous disease was due to the agency of a micro-organism. He proved that a bacillus played a part in the production of tuberculosis which is analogous to that which is played by torula cerevisiæ (yeast bacillus) in fermentation. The tubercle bacillus feeds, grows, multiplies and produces its toxin at the expense of the surrounding tissues, very much in the same way as the yeast bacillus feeds, grows, multiplies, and produces its toxin (alcohol) at the expense of the saccharine solution in which it is placed. The principle discovered by Pasteur in the processes of fermentation and putrefaction was proved, after years of close investigation by Koch, to be absolutely identical in the development of tuberculous disease in the animal body. He demonstrated the bacillus in the tissue, and cultivated the organism outside the body, and observed the formation of the toxin. The same remark may be applied to diphtheria (diphtherization). Diphtheria bacillus grows, feeds, and multiplies on the mucous membrane and there forms its toxin.

"If we compare the processes of fermentation, tuberculization, and diphtherization a little further, we may gain an idea as to the nature of immunity, which is far more rational than any of the numerous and complicated theories and suggestions already proposed.

"After a certain stage of fermentation torula cerevisiæ (the fermenting agent) ceases to act, it becomes inert and falls to the bottom of the vat. Tubercle bacilli and other pathogenic bacteria behave in exactly the same manner. After a certain stage of crowding and production of toxin they become inert, and are at last practically killed by their own poison. The same thing happens in the overcrowding of animals.

"When yeast has ceased to perform its functions in the vat the alcohol (fermentation toxin) which it produced, if not protected artificially, is attacked by another bacterium, the germs of which are always at hand, and it is soon reduced to vinegar, which possesses different properties. Even if more must is added to the vat the acetic acid fermentation will continue. It is well known that the toxin produced by one bacterium can be destroyed or metamorphosed by the action of another. Advantage has already been taken of this power by sanitarians for the disposal of sewage, aerobic and anaerobic bacteria being called into service to do the work desired.

"When the pathogenic bacteria are destroyed by their own poison, and when this poison in its turn is metamorphosed into a simpler compound by other bacteria, in the same way as alcohol is changed into vinegar, the patient is convalescent, and as long as the spores of the second bacteria remains in the blood, the patient is rendered immune;* but if the toxin of the first pathogenic bacteria has been removed by the leucocytes or destroyed by the oxygen of the red blood corpuscles, or, in fact, digested, or if the spores of the second set of bacteria are no longer retained in the circulation or tis-

* Rheumatism produces immunity to tuberculosis, and vice versa.

sues of the body, the patient has no immunity. When the germs which secure immunity become attenuated, the immunity is lessened, and when they are destroyed the immunity is lost for the time.

"In convalescence after diphtheria the toxin, which may be called for convenience sake 'diphtherin,' is no doubt metamorphosed, and its toxic character is destroyed by another ferment, and the new or metamorphosed product may be called 'met-diphtherin.' As long as the met-diphtherin, or its causal agent, remains active or dormant, it confers immunity on the individual body which it occupies. Diphtherin antitoxin is the met-diphtherin obtained from the horse's blood, which confers immunity on the human subject. When this is used at an early stage of diphtheria it damages the vitality of the diphtheria bacilli, and reduces their diphtherin to met-diphtherin, which is harmless.

"Pasteur demonstrated that when grapes are ripe in October a large number of the berries and their stems have their skins covered with spores of torula cerevisiæ, ready to develop under favorable conditions. This happens immediately when the grapes are crushed and the solution is kept at a proper temperature.

"He also demonstrated that yeast can be weakened (attenuated) by nursing it in a weak solution of sugar, until eventually it is unable to cause any fermentation.

"We may also study with advantage the processes of sporulation and vegetation of yeast cells, which are analogous to those of pathogenic bacteria. By the process of sporulation the yeast cell contracts and hardens like a grain of corn, and retains its vitality in this condition for months or years. The same is also true of pathogenic bacteria, which exist either in the state of vegetation or sporulation.

"Professor Sims Woodhead pointed out at our annual meeting last year that diphtheria bacilli may remain dormant in the spore stage in the throat for months. This is an important fact worth remembering, inasmuch as it may account for anomalous outbreaks of acute specific disease.

"Considering the rapidity with which bacteria grow and attain their maturity and multiply, and considering how easy it is to attenuate or increase their virulence, it is logical to infer that the process of evolution may be brought about very quickly, as has already been pointed out. It is therefore natural to infer that, under favorable conditions, *Bacillus coli communis* may be developed into *Bacillus typhosus*, both being alike in size, shape, and appearance, and the so-called pseudo-diphtheria bacillus into diphtheria bacillus, which are also alike in appearance, etc.

"Like the ripe grapes with germs of yeast in the dust on their skins and the surface of their peduncles, we also have germs of specific disease about us which only require certain conditions to develop them. The late Sir James Paget, in his memorable address at the International Medical Congress in London, in 1881, dwelt at some length upon the importance of studying the physiology and pathology of plants to help the advance of knowledge of human pathology.

"Nature always works on definite plans, but with ever varying difference.

"Bacteriology has done much to unravel the mysteries of pathological processes, and it will do still more to advance our knowledge of medicine.

**Therapeutics.**—"Both bacteriology and Listerism have greatly helped to advance our knowledge of the action of medicine. Therapeutics have now been raised in many departments from the plane of empiricism to that of science. Peruvian bark, the active principle of which is quinine, was accidentally discovered to be of great value in the treatment of malarial fever. The discovery was the result of observation, but the knowledge gained was entirely empirical. Prior to the discovery of the hæmamœba and the observation of its action on the red blood corpuscles, and until the Listerian property of quinine was ascertained, we had no idea how the drug acted as a curative agent. It is now evident that it acts simply as an antiseptic in destroying the malarial parasites which are conveyed to the human body by mosquitoes, and it is now very doubtful whether it has any other beneficial action as a therapeutic agent. The world is greatly indebted to Dr. Manson—whose name we were glad to see in the last Birthday Honors list—and to Dr. Ross, for their discovery of the part played by mosquitoes in the causation of malarial fever.

*Salicin.*—"Very much the same remarks may be applied to salicin, salicylic acid, and the salicylates, which are powerful antiseptics. The discovery that these drugs were specially valuable in the treatment of rheumatic fever was accidental also. It is now acknowledged that rheumatic fever is due to a micro-organism which probably gains access to the circulation through the tonsils or mucous membrane of the pharynx. Sore throat is a frequent precursor of acute rheumatism. It is probable that scarlatinal sore throat predisposes the patient to infection by rheumatic micro-organisms, over which the salts of salicin have a lethal action.

"*Mercurial Salts* are the most efficient antiseptic agents we possess in surgical practice, and it may be argued that the therapeutic action of mercury, when administered internally, is to be accounted for to a great extent by its antiseptic property; hence its specific action on syphilis, which is now stated to be a bacterial disease. It has been recognized for many years that mercury is a valuable remedy in tonsilitis, which is also, no doubt, caused by micro-organisms. Dr. Jamieson, of Edinburgh, pointed out some years since (British Medical Journal, 1887) that mercuric chloride is most valuable as a bactericide in the treatment of scarlet fever.

"*Arsenic*, like mercury, a valuable remedy, is a powerful bactericide. It has been stated lately, on very good authority, that it is useful in the treatment of tuberculosis. It is well known as a most valuable remedy in malarial diseases. Its lethal action on other micro-organisms, which we have not yet discovered, may account for its therapeutic value in the treatment of anemia, pernicious anemia, skin diseases, and degenerative changes which are attributed to 'premature old age.' It is possible, and very probable, that micro-organisms are active agents in the production of atheromatous changes in the vascular system. We now acknowledge that the deposit of tartar on the teeth is the product of certain bacteria; even the gouty deposit in various tissues of the body should probably be credited to some as yet unknown bacilli. In any case, the facts before us are sufficient to justify the suggestion as a working hypothesis.

"*Iodine* is another powerful antiseptic agent and a cell stimulant favoring absorption of exudative and inflammatory products; as it possesses these two properties to a high degree, and is readily tolerated by the animal economy, it ranks among the most useful remedies we have in our *Pharmacopeia*.

"*Iron* may act as a powerful antiseptic remedy indirectly. In cases of anemia it improves the condition of the red blood corpuscles which are the carriers of oxygen in the animal economy.

"The local treatment of skin diseases, as well as those of the mucous membranes, may be briefly stated to be a judicious use of antiseptics alone, or in combination with some sedative or stimulating agent, as the case may require.

"Time will not permit me even to enumerate, much less to expatiate on, all the antiseptic agents which we have now at our command.

"We now see that Listerism is as valuable in the practice of medicine as it is in surgery.

**Public Health.**—"The practical application of our knowledge for the benefit of the public health has not kept pace with the great progress made in medicine and in surgery during the last thirty-six years. The Public Health Act of 1875, which was very comprehensive and well conceived, has been of great service in improving the sanitary condition of urban and rural districts; but, in spite of the amending Acts, and in spite of the Local Government Act of 1894, it is now clear that both the law and its administration are defective in many points, and the time has come when both should be improved in order to secure for the public the full benefit of the advance recently achieved in the science of hygiene by bacteriology and the principles of Listerism. Thus, while it is true that every urban rural sanitary authority is required to appoint a medical officer of health, the duties and salary of the officer are left to the discretion of the local authority, expect in those cases in which part of his salary is repaid by the Local Government Board. Rural sanitary authorities are generally satisfied with very little more than the exercise of their power of electing their officer and the fixing of a small salary. The officer, who is as a rule a local practitioner, is allowed to limit his own work as he may think proper; and as the tenure of his appointment is precarious, he is naturally disposed, in the performance of his duties, to interfere as little as possible with individual interests; practically he has no power to correct matters which come under his notice.

"A few months since, a conscientious medical officer of health confessed, in a letter which appeared in the British Medical Journal, that he was paid about £50 a year for doing nothing. The principle of action which he had to observe was 'how not to do it.' The medical officer's reports consist principally of statistics—the number of births and deaths per thousand living, the number of deaths from acute specific diseases, etc.—which are, no doubt, very interesting and instructive, but these details could and should be supplied to the Board of Guardians by the registrar of births and deaths. It would be far more to the point if the medical officer of health were allowed or required to report how many houses were badly drained, how many houses were unfit for human habitation, etc. Speaking generally, the appointment of the medical officer of health in a rural district is very little better than a farce, and waste of public money.

"Now it may be argued that sanitation in rural districts is of comparatively secondary importance since in the country there is plenty of space and pure air; and that, in fact, the mortality in rural districts is lower than in the country as a whole. But there are many fallacies in such a line of argument, and I propose to direct your attention to one. It has become too much the custom to gauge the sanitary state of the country by the general death-rate; a decline in the rate has, perhaps, tended to blind us to facts which lie a little below the surface. It is true that during the last thirty years the annual death-rate of all ages in England and Wales has fallen from 22.25 to 16.3 per thousand living, a gain of about 26 per cent.; but the death-rate of infants under 1 year of age has risen nearly 2 per cent., while the birth-rate has diminished. Nearly half the children born are dead within five years. Increased infant mortality and dimnished birth-rate are two ugly facts which are not to the credit of our country or of modern civilization. The increased mortality among infants is due to diarrhea and enteritis, and we find that the increase due to these two causes is seven times greater in towns than in the country. We also find that the mortality from diarrhea is much greater among infants artificially fed than among those which are fed at the breast alone, or in part. No doubt much of this increased mortality is due to the ignorance and carelessness of mothers and nurses; but it is also an illustration of a defect in our sanitary administration due to the optional character of the acts and regulations already referred to. There are in existence model rules and regulations for the cleanly and sanitary conduct of dairy farms, which, though they have been approved and sanctioned by the Local Government Board in England, are not adopted, or, where they have been formally adopted, are not enforced in rural sanitary districts. The medical officers of health of our great cities complain that, owing to the neglect of rural sanitary authorities, the milk supplied for consumption, especially in the poorer quarters of large cities, is often either decomposing or putrescent.

"The illustration which I have given shows that we must regard our system of sanitary administration as a whole, and must not be content with enforcing sanitary precautions in the cities while neglecting their application in the country districts, from which those cities draw their supplies.

"Notwithstanding the defects in the administration of the Public Health Act, the country is often under a debt of gratitude to sanitary authorities and medical officers of health for protecting our shores from the invasions of plague and cholera from time to time. The importation of plague to Glasgow and to the London Docks, a couple of years ago, is still fresh in our memories, and we have not yet forgotten the feeling of relief we experienced when we were assured that the causal agents had been destroyed and that we had safely escaped a terrible calamity. Great credit is due to the sanitary authorities for their promptitude, energy and determination in the performance of their duty on these occasions. The same may be said of our local authorities generally when an epidemic of smallpox, typhoid fever, or some other infectious disease attacks a populous district. Unfortunately the public is apathetic in these circumstances; it must be hard hit, and many lives must be lost, before it wakes up to realize the situation, and give material help to the medical officer. We are indifferent and accustomed to the endemic and preventable diseases which are always with us, persistently destroying a large percentage of the population. This may be attributed to three causes: (1) The absence of a strong central authority; (2) the ignorance, apathy, and prejudice of the smaller authorities; (3) the objections and the loud protestations of faddists and conscientious objectors to vaccination, objectors to the Contagious Diseases Act, objectors to the advancement of medicine by experiments, etc.—a class of persons who, regardless of the consequence to others, claim freedom to do as they please in matters pertaining to health, freedom to do what is unjust and wrong, freedom to endanger the lives of others.

"And this is allowed in Great Britain, the land of liberty! Gentlemen, this is not liberty, it is undue license and abuse of freedom. Liberty means freedom and security, freedom of action and security to person and property, freedom of action with due regard to others. These conscientious objectors, of whom there are many species in the world, repudiate the conclusions and recommendations of our Commissioners. They claim freedom to break one of the Ten Commandments, and they also disregard one of the great moral principles of Christianity; and, moreover, they are allowed

to have a voice in the Government and the country, and considerable influence in Parliament! It is high time the country should be rid of this tyranny of faddism and ignorance which is responsible for the loss of tens of thousands of valuable lives every year.

"In obedience to the influence of democracy, the tendency of legislation for many years past has been in the direction of decentralization. Unfortunately this has been carried a little too far in the case of the Public Health and Local Government Acts. A healthy reaction is now much to be desired. The Sewage Commissioners, who are gentlemen of the highest abilities, have recently reported, and have pointed out 'the need of setting up a central authority.' All the various committees appointed by the Local Government Board to consider and report on questions relating to food, questions of preservatives, coloring matters, beer materials, and adulterations of food products have made similar recommendations—namely, the necessity of setting up a greater central authority to secure intelligent coordination and direction and a satisfactory administrative control.

"Here the matter ends. The recommendations of commissions and committees are put on one side. Questions affecting the health of communities and of the nation at large are presumably not urgent! Both Parliament and the country are more interested and concerned in trivial and sentimental questions of religious teaching in Board schools than in the physical and mental development of our children. The Opposition, whichever party be in power, apparently prefers wasting the Legislature's time in wrangling over a dispute between a set of recalcitrant quarrymen and their employer to devoting itself to an amending Act to secure better health, longer life, and greater comfort to the community for which they legislate.

"It is evident that the reform we need is greater central authority and greater power to county councils over public health administration within their respective areas, and for this purpose it appears to me that the following scheme would meet the case:

"1. That the President of the Local Government Board should be raised to the rank of Secretary of State, on an equality with the Home Secretary, for the purpose of improving the status of the central authority. It is true that Mr. Long is a member of the Cabinet: but that is not due to the fact that he is President of the Local Government Board.

"There is, I understand, an agitation going on at present to establish a Ministry of Public Health. This at first sight appears to be the very remedy required; but on second thought it is evident that this would defeat its own end and prove a retrograde step. We must remember that the administration of public health in this country is almost entirely local; and we must not forget that the local administrable business of the country, for which the Local Government Board is trustee, and the business of public health are inseparable; it therefore follows that an independent Minister of Health would be in constant collision with the Local Government Board, and the result would be friction and a deadlock.

"2. (*a*) That the county councils, urban and rural sanitary authorites should be under compulsion to appoint medical officers of health who should be precluded from private practice. (*b*) That the county councils should also have power to compel the combination of small sanitary authorities into conjoint areas sufficiently large to secure the services of an efficient medical officer who should give his whole time to public health work. In short, a public health service should be developed to provide the efficient medical officers of health, who are absolutely necessary. The service should be sufficiently tempting to induce some of the best talent in the profession to enter it. The young medical officers of health should begin their work in rural or less important districts, to be promoted, according to merit and seniority, to higher or more important posts with increased salaries. The appointment, in the first place, should be competitive; the tenure of office should be secure; and there should be provision for superannuation. The medical officers of health should have competent sanitary inspectors as at present; their duties should be specified, and they should have the power to carry out the work prescribed for them, very much in the same way as responsible officers in other services. Every medical officer of health should be provided with a bacteriological and chemical laboratory, and the services of an analytical chemist. Laboratories of this kind, properly equipped, which are now few and far between, would also be an invaluable help to general practitioners and specialists.

"One of the duties of the medical officer should be to deliver popular lectures on sanitary questions, and hygiene generally, in his district for the purpose of educating the public on the vital importance of observing the ordinary laws of health. The sanitarian motto should be that which the late Lord Beaconsfield once gave to his party, 'Educate—Educate—Educate.'

"Although it is well to advocate the establishment of sanatoria for the cure of tuberculous diseases, it is far more important and much more logical to go to the root of the evil at once and teach the public the importance of healthy houses, good drainage, proper ventilation, hygienic dressing, and wholesome diet. Prevention is better than cure.

"*A Modest Estimate.*—A moderate improvement in our present sanitary administration would, no doubt, result in a reduction of 1.5 per 1,000 living, in our annual death-rate. Supposing then that the population of the United Kingdom be 40,000,000, the saving of life would amount to 60,000 a year—a total of 1,200,000 in twenty years. A creditable asset even to the British Empire."

### Second Day.

**Infective and Infectious Diseases.**—Dr. F. T. Roberts, of London, gave the address in medicine on this subject. He said in part that it may be taken for granted that when the pathological factor or factors which directly originate a particular disease or group of diseases, about which there had previously been but vague theories and hypotheses, have been definitely recognized, and their true nature established, we may claim that a distinct and important advance in knowledge has been gained. This applies emphatically to the whole range of complaints with which I am now concerned, for the term "infective," according to modern teaching, has come to have a very precise pathological signification, founded on a scientific basis, and the outcome of the researches and experimental investigations of Pasteur, Lister, Koch, and their followers. To this doctrine the medical faculty generally, with but comparatively few exceptions, have given their cordial and uncompromising assent. It affirms that every infective disease is the result of the direct action upon the body of one or more living pathogenic micro-organisms or bacteria, and in many instances it has been positively demonstrated that a specific organism is the cause of a particular disease, and of no other. It must be clearly understood that according to this definition the term "infective" is not synonymous with "infectious," which implies that a complaint is capable of being communicated, either by direct inoculation or contagion, or indirectly in various

ways, from person to person, or from some other animal to man. In short, an infectious disease must be infective; but an infective complaint is not necessarily infectious. He continued thus:

"I need scarcely remind you that a number of contagious diseases have long been known to be due to obvious or easily demonstrable parasites, animal or vegetable, and it is interesting to note in passing that the investigations of recent years have added, and are still adding, to this list, of which actinomycosis may be cited as a conspicuous example. The organisms we are now dealing with, however, are on an infinitely more minute scale, and the profession as a body have to accept in the main what trained bacteriological experts tell us about them, their toxins, pathological effects, antitoxins, and other details. The theory of *contagium vivum* is of very ancient date, but the positive demonstration of the nature of the so-called virus was only started, and has been progressively accomplished well within the last half century; while the investigations which are still going on in all directions are adding daily to our knowledge and to the practical results following therefrom. These investigations, however, have shown that there are still not a few difficult questions to be solved, and we must be on our guard against too hasty conclusions or generalizations on insufficient data. It is a remarkable fact that in the case of some of the most prominent infectious diseases with which we have long been familiar, no definite or specific organism has thus far been recognized, at least so as to be acknowledged by competent and reliable authorities, and we cannot accept the alleged discoveries of such organisms in individual complaints, unless and until they have received the stamp of the approval of such authorities. At the same time we may be certain that they exist, and this fact may be accepted as the basis of a sound working hypothesis.

"When we look back upon the history of medicine during the past half century, but more especially during recent years, we can not avoid being struck with the additions which have been made to the group of infective and infectious diseases, and with the way in which others, though previously known, have come so much more prominently to the front. The multiplication of these complaints has been partly due to the differentiation of diseases which were formerly regarded as identical, as the result of careful and systematic clinical observation and post-mortem examination. It is, however, to the revelations of bacteriology that we mainly owe these additions, which in the first place have brought all inflammatory, suppurative, and septic conditions within the infective group. Among special medical diseases coming under these categories which, according to modern views, are thus definitely classed as infective, may be mentioned pneumonia, rheumatic fever, gonorrheal synovitis, possibly rheumatoid arthritis, malignant endocarditis, certain acute throat inflammations, and different forms of meningitis. But, further, bacteriology has proved conclusively that several unsuspected complaints or morbid conditions, are infective or even infectious, of which the most remarkable are tetanus, tuberculosis, and malaria. Influenza and diphtheria are striking examples of infectious diseases which seem to have developed into terrible scourges within living memory, though they are by no means new complaints, and their prevalence can be easily explained in the light of modern knowledge. Anthrax and glanders have come to the front because they illustrate in a remarkable way certain important points relating to the pathology of micro-organisms. Glandular fever, specially studied in this country by Dawson Williams, is an interesting addition to the acute infectious diseases. I have already alluded to malaria, and I wish now to draw special attention to the fact that the effects of this condition, as well as several diseases always known to be infectious, such as cholera, dysentery, plague, and yellow fever, which originate and prevail chiefly in tropical and subtropical countries, and with most of which we as a nation had formerly little or no direct concern, have nowadays assumed a conspicuous prominence, and have become of extreme practical importance. New diseases belonging to this category have also been, and are still being, brought to our notice, such as blackwater fever, Malta or Mediterranean fever, trypanosoma, sleeping sickness, and beriberi. So important have they become that 'Schools of Tropical Medicine' have been, as you are aware, established in different places for those who need special training in relation to these diseases. The free intercommunication which now exists between Europe and tropical countries, many of them far distant, has brought them to our very door, so to speak, and we are compelled to deal with them seriously, and to do what lies in our power to cope with them. And more especially Great Britain as a nation can not ignore these complaints, as many of the regions in which they prevail form an integral part of this vast empire. We are, I presume, most of us 'Imperialists' nowadays, but in this relationship, at any rate under existing circumstances, no one dare be a 'Little Englander!' We can not evade the responsibilities which the Imperialistic sentiment brings with it with regard to these terrible diseases, whether from the point of view of humanity and philanthropy; of trade, commerce, mining industries, or other remunerative enterprises in which this country is now so actively and widely engaged; of military engagements; or of Christian missionary work. In this connection I can not refrain from calling attention to the itelligent, far-seeing, disinterested, and truly patriotic efforts made by our distinguished countryman, Sir Alfred Jones, a native of Carmarthen, to promote the study of tropical complaints on the spot, as well as at the Liverpool School of Tropical Medicine, and to do all in his power to endeavor to diminish their prevalence and gravity, or even to exterminate them altogether.

**Practical Etiology.**—"I now proceed to deal briefly with certain points relating to what I may term the practical etiology of infectious diseases. With this aspect of the subject all members of the profession, whatever their position or sphere of work may be, are unavoidably and deeply concerned; and there is hardly any branch of medicine in which greater or more beneficent progress has been made, thanks mainly to those who have worked in the various departments of public health, and who have taken an interest in sanitation.

"Now the first question to be determined from the point of view of practical etiology is whether a particular disease is infectious, in the true sense of the term, or not? As I have already remarked, some affections have been in modern times definitely proved to come under this category, which previously could not be so regarded on any scientific grounds, of which tuberculosis is a conspicuous example. The dogmatic statements made on this point about other diseases, which seem to be undoubtedly infective, such as pneumonia and rheumatic fever, must, however, be received with caution until further and more extensive inquiry has been made, though in the meantime it may be well to regard them provisionally as infectious under certain circumstances, and to act accordingly. At the same time we should not ignore or forget the ordinary causes which long experience has taught us are capable of exciting these diseases, such as chill produced in various ways.

"In the next place, it is very desirable, with regard to each individual infectious disease, to have as definite a knowledge as possible concerning its period of incubation; the degree of infectiousness; and the period of infectivity, that is, how long infection lasts in a particular case? In relation to many of the best known affections belonging to this group, these points have been now established fairly accurately, but there is still much to be done in this direction. As regards the degree of infectiousness, undoubtedly the gradations in this respect between different diseases are by no means so clearly recognized as they ought to be, even by the profession sometimes, but more especially by the laity, and consequently one can not help being struck with the want of proportion and tendency to exaggeration exhibited in the way in which certain of these complaints are dealt with. For instance, phthisis is really nowadays looked upon by the large majority of persons as if it were a most virulent infectious disease, equal to smallpox or scarlet fever, which is of course absurd, but the idea has none the less got a firm grip, and is doing an infinite deal of serious harm in different ways.

"The most important and striking advance which has been made in relation to the practical etiology of infectious diseases is in our knowledge of the sources, modes, and channels of infection, both generally and with reference to individual members of the group; of personal predisposing conditions; and of the external circumstances which favor or promote their endemic and epidemic prevalence. On these matters our information was, within my own recollection, extremely vague and indefinite, and many most significant facts, with which we are now quite familiar, were utterly unknown and even unsuspected, except by a few intelligent observers and earnest workers.

"The question of the communicability of certain infectious complaints from person to person through the atmosphere is an extremely important one, especially when a number of individuals are aggregated together; as well as the distance to which the contagium can be thus conveyed, and the agencies which assist in its dissemination. This question is by no means settled in not a few instances. Let me refer more particularly to typhoid fever and smallpox. While typhus fever has always been regarded as a disease strongly infectious from person to person, typhoid fever has been practically dealt with by the large majority of the profession as being free from danger in this way. Now, however, the tendency undoubtedly is, and probably rightly, to be much more careful as regards enteric from this aspect, and there is a growing objection to the admission of typhoid patients into the ordinary wards of general hospitals. Smallpox is still more important. Of course it is a fact familiar to all that this complaint is highly infectious through the atmosphere, but how far it can be thus carried, particularly from a smallpox hospital or hospital ship, and the influence of winds in conveying the infective agent, is another matter, and may involve troublesome or even momentous consequences. I have noticed in the medical press recently directly contrary opinions on this question, expressed by those who apparently have had equal experience and opportunities of arriving at a practical conclusion. How far emanations from drains, sewers, defective water-closets, and the like, can produce so-called 'blood poisoning' and other indefinite infective conditions, is another question which needs clearing up.

"Passing now to the more practical results of modern investigations as to infection, the following facts are worthy of special attention:

"1. As a starting point infective micro-organisms have been found and demonstrated in the blood; in certain secretions: in the excreta, urine as well as feces; in the cutaneous structures or shed epithelium; possibly in the expired air; and in specific lesions, morbid products, and discharges from the body of various kinds. Hence we can readily understand how and why most of the diseases with which these organisms are associated are likely to be transmitted from individual to individual; how the infected materials may contaminate fomites, and be thus conveyed far and wide; how they retain their activity in a dried state for an indefinite period, thus rendering apartments or other places infectious; and how they may be 'airborne,' being carried about by atmospheric currents or winds, and afterward either inhaled or swallowed by persons, it may be, far removed from the original source of infection, remote epidemics being thus not uncommonly originated.

"2. The communicability of certain grave diseases by the contamination of drinking water in different ways, but especially by admixture of infected excreta, is an established fact the importance and far-reaching consequences of which it is impossible to estimate or realize in any adequate degree. Why such contamination should take place is often obvious enough, but it is rather startling to be told, as we have been within a recent period, that unsuspected and most inviting 'spring water' may be a highly dangerous source of enteric fever. I have a very vivid recollection of an epidemic of cholera, and another of enteric fever, in Carmarthen when I was an apprentice, and in the light of modern knowledge there can be no doubt but that they were the result of infection through an excellent 'spring water' in common use, which had become contaminated with the specific excreta. While we are now all so familiar with the dangers of infected water, it required some hard teaching to convince the profession and the laity of its reality, and we ought never to forget the excellent work done by Snow Beck, Ballard, and other pioneers in relation to this matter. Even at the present time, moreover, my experience has led me to the conclusion that these dangers are by no means always appreciated as they ought to be, and I have met with not a few glaring instances of the injurious effects of ignorance or carelessness. In this connection I may refer for a moment to the vigorous and praiseworthy efforts of my former pupil and friend, Dr. Leigh Canney, who at any rate is fully alive to the evils and risks of water infection, to establish a Royal Water Corps as a special section of the R.A.M.C., the functions of which it would be to prevent enteric fever, dysentery, cholera, and diarrhea. It does not look, however, as if his project had 'caught on' with the governing bodies, and no doubt there would be serious practical difficulties in carrying it out.

"3. One of the most striking additions in modern times to our knowledge regarding the conveyance of infection is in relation to food. In this connection milk and its products stand out very prominently, not only on account of their frequent contamination by infectious materials, probably mainly from the deliberate addition of tainted water to milk, but also because this valuable food may convey organisms directly from diseased animals by whom it is secreted. No doubt you are all familiar with the present controversy as to the communicability of bovine tuberculosis to the human subject in this way: but, notwithstanding Koch's dogmatic negative statement, more recent investigations, prominent amongst them those of Professor Hamilton, of Aberdeen, and Mr. McLaughlan Young in this country, seem to have demonstrated conclusively that this authority, in spite of his high scientific claims and standing, is entirely wrong. At any rate it would be a grave mistake to act on Koch's view, or to ignore in the

slightest degree the possibility of the conveyance by milk of the infective agents of tuberculous or other diseases. I will merely allude in passing to the probable danger in some cases of infection through meat, fried fish, uncooked vegetables, or various foods accidentally contaminated, as from being kept in infected rooms, or it may be by winds carrying organisms from a distance. But what shall I say about shellfish? Dare I whisper in this neighborhood the word 'oysters'? Unfortunately there can be no doubt but that these 'luxuries' are not uncommonly potent agents in originating enteric fever; and the same statement applies to the more humble and democratic mussels, cockles, or even periwinkles, as well as possibly to lobsters, crabs, and the like. May I venture to suggest that it is extremely desirable for all concerned, that everywhere the utmost precautions should be taken to prevent as far as possible these most desirable and valuable articles of food from being contaminated by sewage of any kind; and the deliberate feeding of oysters on such materials, for commercial purposes, can not be too strongly condemned, and ought to be put a stop to by the most stringent legal measures.

"4. The rôle which different animals play in the transmission of infectious diseases to man is another aspect of the subject upon which modern observations and researches have thrown remarkable light. Of course the relationship in this respect of such diseases as hydrophobia and glanders has long been recognized. The idea of direct infection through the milk or flesh of infected animals is of comparatively recent date. The danger of infection being carried directly by domestic animals, such as birds, cats, and dogs, from person to person, or perhaps because they themselves are suffering from certain diseases, is not yet appreciated as it ought to be. The rôle played by such unwelcome 'large vermin' as rats and mice in relation to plague, and probably some other complaints, is now familiar to all. Flies, cockroaches, and the smaller but too well-known personal vermin may no doubt be instrumental in conveying infection in certain cases, and flies may thus taint food. But the most remarkable and important revelations which modern investigators have given us as to the transmission of infection by animals are those relating to mosquitoes. The discovery and demonstration of the connection between these minute torturers of humanity and malaria, in which Sir Patrick Manson and Major Ross have taken such a prominent part, has already worked incalculable good, and promises in the future to revolutionize the conditions of life in many parts of the world, to the inestimable advantage of the communities who are native to the district, as well as of Europeans whom circumstances compel to reside there. The same statement applies to yellow fever, and probably to other affections prevailing in climates and localities where mosquitoes abound.

"5. The question of the relation of infection to soil, place, and particular houses or groups of houses, is a very important one, but about which there is at present much that is uncertain and indefinite, and that needs to be worked out more fully before any positive conclusions can be arrived at with regard to individual diseases. The fact that the tetanus bacillus comes from the soil, being especially associated with garden earth or horse-dung, is well established, and was a most interesting and important modern discovery. Beriberi is regarded by Manson as a 'place disease,' due to a toxin produced by a living germ operating in some culture medium outside the body. Of course, houses or rooms may, when once infected with the organisms of well-known diseases, retain them indefinitely, and thus be the means of originating similar affections after long intervals.

"6. Another most important aspect of infection, from a practical point of view, is the fact that we are every one of us always carrying about in various parts of our bodies microbes, which while habitually innocuous and non-virulent, may under favoring conditions, so far as they are concerned, become extremely virulent, or possibly specific, to our personal undoing; or we may even be harboring in our mouths, throats, noses, ears, and thereabouts specific germs by which, quite unintentionally, we are liable to infect others at any time, while we ourselves go scot free. It is certain that very dangerous germs may lie dormant for an indefinite period in the human body, such as the bacilli of diphtheria, influenza, or tubercle, or their spores, and either lead to unexpected auto-infection, or to the corrospending specific disease in others. When suppuration is set up in any part of the body, moreover, it is wonderful how disagreeable the different organisms can be, in the way of migrating to various other structures, and producing a similar condition in connection with them.

"7. I must just refer, lastly, to the progress made in our knowledge of the channels of entrance of microbes into the system, and the modes in which they are disseminated. Here again the mouth, throat, and neighboring parts come into unpleasant prominence, especially the tonsils, in connection with scarlatina, rheumatic fever, tuberculosis, actinomycosis, and other diseases. The dissemination of the organisms by cells, the blood stream, and the lymphatic channels is also an important fact positively demonstrated; and in this dissemination embolism not uncommonly plays a conspicuous part.

"I now pass on to refer briefly to other modes of investigation not uncommonly of much diagnostic value in relation to infectious and infective diseases, which are also comparatively easily practised, and are supposed to be carried out more or less as a matter of routine in ordinary medical practice. I allude to physical examination, especially as applied to the chest and abdomen; and examination of the urine. Of course, in the clinical study of many inflammatory diseases and special affections now included under this category—for example, pneumonia or cardiac rheumatic manifestations—skilled physical examination is essential; while it is also of great help in the detection of complications and sequelæ, to which it must be noted attention may not be attracted by any prominent symptoms, and consequently they are very liable to be overlooked unless the practitioner is constantly on the alert to detect them by the systematic employment of this method of investigation. The necessity for examining the urine at frequent intervals would, I suppose, be generally recognized in scarlatina, or perhaps even in diphtheria, for well-known reasons; but this measure is not always carried out so regularly or systematically as it might be in other complaints of an infectious nature. As a special test applied to urine I may remind you of Ehrlich's 'diazo-reaction' for typhoid fever; but it is not reliable, even when present, as it may be met with in other affections.

"The special methods of diagnosis applicable to infective and infectious diseases which modern scientific researches have brought so prominently before the medical profession have naturally attracted great attention and excited keen interest. It might be thought an occasion like this would afford a most suitable opportunity for discussing these methods at some length, and endeavoring to estimate their practical advantage up to the present time and their future possibilities. I have preferred, however, to devote most of the time I could give to the clinical aspect of my subject to the more common modes of investigaton, for reasons already sufficiently indicated. I have, therefore, left myself but

little space to deal with these more scientific methods, which I may remind you often require the help of an expert before their results can be safely relied on. I shall content myself with merely giving the following summary of these methods and their objects, mainly coming under the head of bacteriological diagnosis. They include:

"1. Examination of the blood, both as regards its normal constituents, especially the number of leucocytes and the relative proportion of different kinds of cells, the blood plates, and the presence of abnormal corpuscles; and from a bacteriological point of view. The spirillum of relapsing fever and the malarial parasites are prominent examples of pathogenic organisms found in the blood, and the latter have to be observed and studied during the changes they undergo; along with their effects upon the red corpuscles and the formation of pigment.

"2. The further detection and microscopical demonstration of organisms, specific or non-specific or both, either obtained from the tissues of the body; or contained in secretions, feces and urine, various discharges, sputum being particularly noteworthy, and other morbid products of different kinds, fluid or solid, of which diphtheritic material is a conspicuous example. The organisms are not only identified by their morphological characters, but also as a rule by their peculiar staining reactions.

"3. Separation or isolation of the microbes, which are afterwards grown on suitable media, in order to obtain cultures, the results being often highly characteristic, both to the naked eye and on microscopic examination.

"4. Application of the 'segregation' and 'agglutination' tests in relation to the blood serum of the patient, which is most familiar to us in Widal's test for enteric fever.

"5. The observation of the effects on the individual of the inoculation of certain products of the specific microbe of the disease from which he is supposed to be suffering, as in the so-called 'reaction test' with tuberculin for tuberculosis.

"6. The pathological results of inoculation of animals, either with the organisms themselves or with their toxins, which in some instances are essential for positive and accurate diagnosis, lesions of a definite and characteristic nature being thus produced, as is well-exemplified by diphtheria.

"A rather awkward question, but one of extreme practical importance to the profession, has been recently forced upon our notice, which I can not altogether pass by. In the British Medical Journal for March 7 an abstract is given of a disquieting statement issued by the Hospitals Committee of the Metropolitan Asylums Board as to the number of cases of mistaken diagnosis sent to the Board's hospitals as notifiable during the three years 1899-1901. The subject is very ably, fairly, and sensibly dealt with in a leading article in the British Medical Journal of March 14, on the 'Diagnosis of Notifiable Diseases,' which might be read with advantage by all who are directly interested in the question, or indeed even by the laity generally. They do not in the least realize the difficulties which confront the practitioner, with whom I have the deepest sympathy; and residents at the infectious hospitals can not be too careful and particular not to hurt the feelings of their brethren in the profession more than can be possibly helped. Of course any carelessness in diagnosis in relation to infectious diseases is inexcusable; but really young practitioners are not responsible for the fact that they are not so familiar with these complaints clinically as would be desirable, and that many of them have to gain the requisite experience after they have entered upon their active professional duties. May I venture to suggest that while the modern medical student has immense advantages, he labors under a decided disadvantage from this point of view, as compared with those of us who served an apprenticeship, and became familiar with at any rate the more common infectious diseases, even before we started upon our regular studies at a medical school. As a matter of fact he gets very little opportunity of gaining practical knowledge of most of these complaints during his period of studentship, and has to fall back upon so-called 'post-graduate instruction,' if he desires further and more special training and experience."

**Treatment.**—Speaking of the advances in treatment he dwelt particularly on

1. *Hydrotherapy and Allied Methods.*—"No doubt you are aware that Dr. James Currie of Liverpool, to whom I have previously alluded, strongly advocated and carried out the treatment of fevers on a considerable scale by baths and douches. This treatment fell into practical desuetude, and, indeed, was generally looked upon with aversion and dread. In modern times, however, it has not only been revived, but numerous other methods for applying cold to the body, either generally or locally, have been added, not only by means of water, but also of ice and cold air. These methods are now generally recognized and extensively adopted, probably more on the Continent and in the United States than in this country, even in the treatment of many of the ordinary fevers, but especially in the more severe cases; and the local application of ice is strongly advocated in acute pneumonia and other inflammatory infective diseases. While of great value as antipyretics they have other important beneficial actions, which I need not now specify. Regarding hydrotherapy and allied measures in the treatment of infectious diseases, I would remark that every medical practitioner ought to be familiar with them, and be able and ready to carry them out when required. The milder methods, such as sponging the skin or applying ice locally, are easily practised, and are often of the greatest service. Personally, however, I do not advocate or employ the more severe methods as a routine system, as many do; and I feel sure that I have met with serious injurious consequences from such a practice. On the other hand, their essential value in saving life under grave conditions can not be too strongly insisted upon.

2. *Use of Alcohol.*—"I now come to a question in relation to the treatment of infectious diseases and cases, both generally and individually, which demands the most thoughtful consideration, namely, that of the administration of alcohol. And I feel bound to take this opportunity of stating emphatically that when we, as members of the medical profession, approach from any point of view this alcohol question, we ought to do so under a deep sense of responsibility, but at the same time rationally and without undue bias one way or the other. At a large political meeting held not very long ago an eminent statesman was contrasting imperial with local questions, and giving his own ideas about their relative importance, founded upon certain personal experiences. Amongst the local questions he mentioned 'temperance reforms,' and his allusion was received by the audience with loud laughter! I venture to say that such is not the spirit in which this grave subject ought to be regarded at the present day by any community; and, at any rate, the medical profession as a body is bound to sympathize with and encourage every effort made in this country to check the terrible evils produced by intemperance, which confront us in such overwhelming and appalling degree on all hands in our daily expe-

rience, and to do our utmost to promote sobriety amongst all classes, however hopeless the task may appear to be. And from this point of view we should always be most careful to avoid ordering stimulants to patients not accustomed to them, unless they are, in our individual opinion, really necessary; while it is well always to give very definite instructions as to their administration. There is an influential body of the medical faculty in this and other countries, some of them of the highest professional and scientific standing, who absolutely and entirely object to the use of alcohol under any circumstances, and for these ladies and gentlemen I entertain the highest respect. As you are probably aware, an 'International Medical Manifesto' against the use of alcoholic liquors was issued a short time ago, which roused resentment and a strong protest on the part of some members of our profession. To a certain extent I share their feelings, for, with all due respect to the opinions and statements expressed in that manifesto, I think those who signed it have gone too far, and I regret that I can not altogether agree with them. At any rate, so far as infectious diseases are concerned, I must express my own strong conviction that in a large number of cases the judicious administration of alcohol is of the greatest service, and I have seen a considerable number of grave, and sometimes almost hopeless cases in which I have no hesitation in affirming that recovery was due to the use of alcoholic stimulants, not uncommonly in considerable quantities. Moreover, they are often of conspicuous value during convalescence. With ordinary prudence and care it is quite easy to avoid establishing a habit of taking stimulants in the case of patients who have been previously abstainers. While thus expressing my personal opinion in favor of the use of these agents in infectious diseases under suitable circumstances, I feel bound, on the other hand, to warn against their employment as a matter of routine, and venture to urge that the most thoughtful and conscientious consideration should be given to every individual case before ordering them.

3. *External and Local Treatment.*—"The treatment of external or local manifestations of particular infectious dseases, such as scarlatina, smallpox, or diphtheria, affords legitimate ground for differences of opinion, and I must confess it is often puzzling to determine what is best to be done for such conditions when one reads the different methods of treatment advocated by different experienced authorities. I can not refer to them further now, and must content myself with saying that the measures to be adopted must be determined very much by the particular views of the practitioner, guided by judgment and discretion, and modified by the special circumstances of each case. Antiseptics and disinfectants are employed with great advantage as local applications for various purposes. How far the light treatment, the X-rays, or particular color rays are going to help us, can not be definitely determined at the present time. Just now the subject has come very prominently before the profession and the public, and the 'red-light treatment of smallpox,' which, however, is by no means a novelty, so strongly advocated by Professor Finsen in the British Medical Journal for June 6, is attracting special attention, as well as some adverse criticism. What we may expect, also, from that wonderful, newly discovered element—radium—it is impossible to foretell, but we must be on our guard against accepting statements as to its marvelous curative effects by irresponsible observers.

4. *Vaccines: Serumtherapy.*—"What would, no doubt, be generally regarded as the most vitally interesting and important question of modern times, bearing upon the prevention and treatment of the entire group of infective diseases, is that of 'serumtherapy,' using the term as an inclusive one, which has come as the natural outcome of the microbic theory, and is founded, on the whole, on reliable bacteriological researches and experiments, supported by the results of practical experience in living subjects. Time will only permit me on the present occasion to touch the fringe of this most attractive and fascinating subject, and I will only ask you to bear with me while I remind you for a moment of what this method of treatment consists, and what are its objects and aims. Following Sims Woodhead's classification, the materials used are divided into—(1) Vaccines, which are either cultivations containing pathogenetic micro-organisms with toxins, or toxins only; or the tissues or fluids of an animal suffering from a particular infectious disease. (2) Antisera, which may be antitoxic only, neutralizing the toxins; antibacterial or antimicrobic, acting directly upon the organisms; or in some instances having both actions. The comparatively recent investigations of Professor Macfadyen and Mr. Sydney Rowland with regard to the immunizing power of the cell plasma of the typhoid bacillus, and the effects of repeated injections of this substance in rendering the blood serum of an animal both antitoxic and bactericidal, are very remarkable, and promise great results in the future. Up to the present time these therapeutic agents have been practically only employed by inoculation, being usually injected subcutaneously, but exceptionally more deeply, or into special structures. I note, however, that the antidiphtheritic serum has lately been recommended to be administered by enema, or even in pastils. Vaccines and antisera are employed either for the purpose of producing temporary or permanent immunity against an individual disease; or for the actual treatment of certain complaints or morbid conditions, either acting as definite 'cures,' or so modifying their course that their severity and dangers are materially lessened, their progress is hastened, and their mortality greatly diminished. The large majority of these agents are specific, being only used in relation to a particular disease; but the antistreptococcus serum has been found of service in various affections, and so-called 'Coley's fluid' is also non-specific. The diseases thus treated with which we are most familiar are smallpox, as prevented or modified by vaccination and revaccination, hydrophobia, diphtheria, tetanus, enteric fever, scarlatina, cholera, pneumonia, septicemia, anthrax and glanders, plague, tuberculosis, leprosy, and cancerous or sarcomatous growths, assuming them to be infective. Now, no one who has watched the course of events during recent years, and who is unprejudiced, can doubt for a moment or fail to acknowledge the immense value of this modern therapeutic method in relation to some of these complaints; there are others, however, in which thus far it has entirely failed in its objects; while in others still it is on its trial, and those who are in a position to speak authoritatively differ widely in their views and conclusions as to its efficacy in some of the most important infectious diseases. Personally I confess that I am inclined to regard not a few of the positive statements made with a skeptical mind, and I think we ought to be particularly careful in accepting and acting upon them at the present time, remembering the suspicious and not too friendly attitude of a large number of the influential laity toward the medical profession. At the same time, it can not be too strongly insisted upon that every member of the medical profession ought to avail himself or herself to the full of any method of treatment which bacteriology offers us, provided it has been scientifically and practically proved and demonstrated to deserve our confidence. It is not for us, in the present

state of the law, to deal with the 'conscientious objector,' but I emphatically affirm that any individual practitioner who wilfully and with intent neglects or is in actual antagonism to vaccination and revaccination as a protection against smallpox, may be justly regarded as guilty of a grave dereliction of duty, and is responsible for serious mischief, the results of which are but too evident to any unprejudiced observer. The same remark certainly applies to the neglect of the vaccine or antitoxin treatment for diphtheria, hydrophobia, tetanus, and anthrax. The opening of the new building of the Jenner (now the Lister) Institute of Preventive Medicine encourages the hope that this country will not in the future be behind others in advancing this most important and promising branch of scientific and practical medicine.

"It was my original intention to offer some observations on the prevention of infectious diseases from a general standpoint, but I have already trespassed too long upon your patience, and must content myself with a few closing remarks. I venture to affirm that the predominant aim of the medical profession as a whole is essentially beneficent. In support of which statement I can confidently draw attention to the deep interest exhibited by its members in this question, and to the efforts made by them, not only to limit and prevent these complaints in a general way, but to eradicate and exterminate those with which we may be thus able to cope effectually. This is no sham or pretence on our part, but an honest and straightforward policy and purpose, to which not a few devote their lives and best efforts, which ought to be a rebuke to scoffers and slanderers, of whom there are many. I will go further, and say that in dealing with infectious diseases, medical practitioners and scientific workers often exhibit a brave, courageous, and self-sacrificing spirit, which is worthy of our highest esteem and admiration. To go into the midst of a virulent epidemic, and fight against it day and night, often under the most trying and adverse conditions, which is no uncommon experience, is no trifling matter; and I could give many instances of individual courage and devotion, as well as of voluntary exposure to grave personal danger, sometimes ending fatally, which were truly heroic. Even the bacteriological researches in laboratories, which are intended to benefit humanity, are a source of danger—witness the cases of fatal infection with tuberculosis, and the death of the young Austrian doctor who not long ago succumbed from plague while working in Berlin. But I feel bound to pay a special tribute of respect and admiration to those who have gone forth to pestilential climates, and often under great hardships, or even by submitting themselves to dangerous personal experiments, have done such marvelous work in diminishing and controlling, or in some districts even exterminating, malarial and other diseases which were formerly the cause of destruction of human life on a vast scale, as well as of such extensive and profound deterioration of health.

"What will be the future progress of events in relation to the prevention of infectious diseases it is impossible to foretell or estimate, though the forecast is in certain directions decidedly hopeful. I venture, however, to submit that we as a profession should be extremely cautious as to what we say, and should avoid a too 'cheery optimism,' in the way of making promises and predictions which, recognizing the very nature of things, the conditions under which humanity exists, and the difficulties which so-called civilization brings with it—experience and common-sense must tell us are, to say the least, extremely rash. On the other hand, let us never relax in our efforts to promote the good cause, and to encourage, develop, and enforce every measure, scientific or practical, which has for its object the mitigation or prevention of those widespread and often terrible infectious diseases which now add so enormously to the death-rate, and which, even in cases of recovery, leave such serious after-consequences amongst large numbers of the community. And this we must do in spite of opposition, however powerful, persistent calumny, vicious attacks on our motives, or even being called foul names. There are numerous 'antis' about just now, but for downright insolence and impudence the antivivisectionists 'hold the field.' They have the most astounding faculty and capacity for fabricating statements for which there is absolutely no foundation, for distorting facts, and for cooking statistics, and they stick at nothing. Let us treat them and their hysterical outbursts with the contempt they deserve. Our duty is plain enough. Not only must we work on steadily as a profession in the direction I have indicated, but we must earnestly strive to gain the confidence and cooperation of influential individuals and communities, and to guide them on intelligent and rational lines.

"I have been asked to speak in this address in support of the appointment of a Minister of Public Health. I note that you, Mr. President, are not in favor of such an appointment; but personally I really do not feel competent to speak one way or the other. You have sketched a scheme with regard to the practical and official working of the Public Health Department which appears to have sound principles underlying it; and at any rate some change is obviously necessary. In the meantime, however, we must do what we can to educate and influence borough and county councils, and other public bodies which are concerned with sanitary matters, as well as members of both Houses of Parliament and to stimulate them to do their duty. Thus will we, as members of a self-sacrificing and noble calling, while endeavoring in our individual capacity to perform conscientiously and intelligently the duties which devolve upon us in relation to actual cases of infectious diseases which come before us in our several spheres of practice, be further collectively and with concerted action doing what lies in our power to promote the health and well-being of our fellow creatures on a large and comprehensive scale, and to avert or mitigate the effects of those grave maladies which are now such a scourge to humanity."

**Evolution of Abdominal Surgery.**—Dr. A. W. Mayo Robson, of London, gave the address in Surgery, basing his remarks on his observations extending over a third of a century and his experience in 2,000 operations. He said:

"It is clearly impossible in a short time even to briefly record all the advances made in surgery, but in my work as a general surgeon I have also had the privilege of taking part in the development and progress of a special branch, abdominal surgery, than which nothing could better exemplify the great changes that have occurred during the thirty-three years which I am considering; for, in the early Seventies, abdominal diseases were practically always treated expectantly, and if we look at the reports of 1870 we shall see that, as judged by results, it was perhaps just as well that surgery had then no business inside the abdomen.

"As knowledge increased, and surgery became more scientific, many of the diseases in question became surgical either from the beginning or at a later period in their course, so that to-day abdominal surgery is a subject of the first importance. Not only has treatment advanced by leaps and bounds, but our knowledge of abdominal diseases and their successful diagnosis has

enormously increased, partly by pathological advancement generally and by experimental research, but also by philosophical observations on the operating table and the study of disease in the living subject—in other words through biopsy instead of necropsy. The time was when the physician thought he had done all that was necessary when he had arrived at a probable diagnosis, and he philosophically waited until his hypotheses were proved or disproved in the deadhouse; treatment was left to the junior as being quite a secondary matter, and I am bound to say that in abdominal diseases that were not merely functional, and that could not be treated in the out-patient department, the estimate placed on treatment was often correct.

"Then ovarian disease was generally known as a form of dropsy, and was either treated by tapping, when the pressure became so severe as to demand some relief, or seeing that tapping was at times fatal or only gave a temporary respite, the greater number of cases went untreated. The surgery of the intestines, except for strangulated hernia, was not thought of, and uterine, renal, gall-bladder, stomach, liver, and pancreatic surgery were hardly dreamt of as possible. In 1870 an attempt was being made in some of the general hospitals to emulate the example set by certain pioneers, such as Clay, of Manchester, Spencer Wells, of London, and Keith, of Edinburgh, but with what result? It is interesting to note the following facts:

"In St. Bartholomew's in 1870 there were 3 ovariotomies, all fatal, and 20 cases of herniotomy in which the sac was opened, with 9 deaths. In Guy's there were 5 ovariotomies with 3 deaths, and 19 herniotomies with opening of the sac, of which 11 died. In St. Thomas's there was 1 ovariotomy, which died, and there were 14 herniotomies, of which 8 died. In St. George's there were 2 ovariotomies, both of which died, 1 colotomy, which died, and 20 herniotomies, of which 8 died.

"In the same reports there was always found a special record of the number of cases which are now so rarely seen. For instance, in one of the reports for 1870 there were recorded 53 cases of erysipelas, 20 of phagedena, 93 of diffuse cellulitis, and 4 cases of secondary hemorrhage after operation, which at the present time would be sufficient to condemn any surgical clinic; yet this record was no exception, as all the hospitals furnished similar reports.

"It would be invidious to compare the work of the various hospitals, as shown by the reports of 1902 published this year, but in one of the chief hospitals I notice a record of 40 ovariotomies with 39 recoveries, of 18 hysterectomies with 17 recoveries, of 241 herniotomies including strangulated hernia as well as radical cure of the hernia, with 233 recoveries, of 16 gall-bladder operations with 15 recoveries, a record of which no hospital in the world need feel ashamed.

"The rise and progress of abdominal surgery has centered more around ovariotomy than any other branch of work, hence it may be of interest to review for a moment the evolution of that operation, for it has been the battlefield of abdominal work.

"The history of ovariotomy is one of international importance, for the performance of the first operation has been claimed both by Great Britain and America. Williams, of Basle, in 1731 seems to have recognized the possibility of ovariotomy, and Hunter in 1762, with characteristic genius, actually suggested the modern operation, urging a small incision, the tapping of the cyst, removing it and ligaturing the pedicle. Houston, of Glasgow, operated for ovarian tumor before Mc D.well, but according to the best authorities McDowell, of Kentucky, performed the first complete and successful ovariotomy in December, 1809. Both in America and Great Britain the operation struggled into existence in the provinces before it engaged the attention of surgeons in the great medical centers, and in 1825 Liston boasted that Lizars (who had done several not very successful operations in Edinburgh) did not set about any such operations in the infirmary after he became attached to it. The medical papers of that day also condemned it absolutely.

"Although Clay, of Manchester, between 1842 and 1850 had chronicled 33 operations with 21 successes, a 36.3 per cent. mortality, and Spencer Wells in his work up to 1870 showed a mortality of 25 to 30 per cent., yet in that year, in the large general hospitals, the mortality was no less than 81 per cent. I distinctly recollect as a student the question being raised as to whether ovariotomy ought to be continued, and I remember as a dresser that the easiest cases, where there was a healthy peritoneum free from adhesions, were almost certain to die.

"From 1870 I followed keenly all the controversies on the subject, and a little later took the opportunity as a post-graduate of visiting Keith in Edinburgh, Spencer Wells in London, and some years later Lawson Tait in Birmingham, from all of whom I learned valuable lessons. Keith, a thorough believer in antiseptic procedures, in 1884 published a series of cases with a 9.11 per cent. mortality, but later he had 80 consecutive recoveries in completed cases, while Tait published an account of 405 cases with 33 deaths, an 8.1 per cent. mortality, and in 1885 he had had 139 cases without a death.

"The success in private practice and in the smaller hospitals was so much greater than in the general hospitals that the question was raised as to whether such operations ought ever to be performed in a general clinic. Yet what do we see to-day—last year there were 67 ovariotomies including malignant and suppurating cases performed in the Leeds General Infirmary (with which until recently I was actively associated) with only 3 deaths, otherwise a mortality of 4.4 per cent., which I find to be about the average in general hospitals; for although in private practice, where operations are performed at an earlier stage and in patients not worn down by suffering and hard work up to the last moment, better results may be shown, yet it may now generally be fairly stated to any patient suffering from ovarian cyst that her chances of recovery are fully 95 out of the 100, for excluding accidents such as syncope, embolism, and pneumonia, which are often unavoidable, there is no reason why any patient should die after an ordinary ovariotomy skilfully performed.

"It is interesting to note the changes that have brought about these results. I remember in the early Seventies, when there was no special preparation of ligatures, which were of silk used straight out to the storage cabinet, and often handed to the surgeon by the theater porter, who might even be post mortem attendant; when little care was spent on cleansing the surgeon's hands and none on cleaning the patient's skin; when a perfunctory washing was supposed to be sufficient for instruments, and a very superficial cleansing to be ample for sponges, which were doubtless the most fertile source of mischief. The surgeon then wore a non-washable operating coat to protect his own clothes from being soiled, and not, as now, a sterilized overall to guard his patient from contamination.

"The introduction of antiseptics started the change, but at first and for some years, carbolic acid was by many thought to act like a fetish, and to cover a multitude of sins; a mere dipping of the hands in a 1-in-20-to-40 solution was considered a means of cleansing, the soaking of catgut ligatures in carbolic oil was

thought to be a sufficient preparation, and the skin of the patient was for a long time ignored as a source of infection. Moreover, the improper use of the carbolic spray, which was allowed to play straight into the opened abdomen, was itself a source of danger, undoubtedly causing many deaths, though it was not dangerous when properly employed, as, for instance, by the late Thomas Keith, who, while using antiseptics, including the spray, yet took every care to cleanse his hands and instruments and the patient's skin; and in this way, so early as 1884, was able to record such good work. In the Eighties, following on the same lines, I was able to report my first series of 83 cases in a general hospital with 4 deaths, only two of which could be referred to as wound complications, though later I had a consecutive series of 103 cases in private, with only one death, and that patient was operated on when suffering from acute peritonitis.

"Then came a reaction against the use of antiseptics, and a veritable crusade, with much acrimonious writing, was led off by Lawson Tait, who argued that antiseptics were not only unnecessary to success, but were actually injurious. By Dr. Bantock, who held similar views, asepsis was carried out quite early; and I remember, when seeing him operate at the Samaritan Hospital, the infinite care he took in cleansing his hands and everything that came in contact with the wound; but in the late Lawson Tait's case his success came from another discovery, for, although he was by no means what we should now call an aseptic surgeon, as shown by his results in other than abdominal wounds, his genius found a different way, for he taught us the value of natural drainage through the intestines, and the importance of the avoidance of morphine. He made a routine practice of purging after operation, and so avoided that distention which used to kill so rapidly in early ovarian work. Had purging and the avoidance of morphine been adopted in the early Seventies I have no doubt that the large mortality of that day would have been materially lessened. Over and over again as a student I have seen patients killed by intestinal paralysis induced through morphine, who, I now know, might have been saved by a dose of calomel and Epsom salts. Other lessons I learnt from Lawson Tait were the value of rapidity in operating and of thoroughness in the removal of disease, for in early work on the uterine appendages it was not at all uncommon for the surgeon to be deterred by adhesions, and to rest satisfied with the drainage of pus tubes and cysts, instead of their complete removal, with the result that such patients either remained invalids or died more rapidly than if they had never been treated. I followed the evolution of the treatment of the ovarian pedicle by means of the external clamp (Wells), the cautery (T. Keith), the *écraseur* (Jessop), and lastly, by ligature with dropping of the pedicle, which we all now adopt, and which Baker Brown was the first to advocate.

"Under perfected technic, and a judicious combination of asepsis and antisepsis, ovariotomy has become one of the most successful major operations in surgery, and has paved the way for other equally great triumphs within the abdomen.

"The discovery of the frequency of perforative appendicitis, of perforating gastric ulcer, and of other peritoneal catastrophes is gradually abolishing the term acute peritonitis for the more rational one of acute peritoneal infection, for the treatment of which surgery alone is of any use, and even for it to be of service operation must not be long delayed.

"These more rational views of pathology and treatment have originated and developed with recent years, and I can recall case after case, during my student days, in which peritoneal catastrophes ended fatally, where now we should by timely interference give a very fair chance of life. Could anything show this more definitely than the results of treatment of perforated gastric ulcers, which if operated on at once would have hardly any mortality, if within 12 hours of rupture have a mortality of 16.6 per cent., if within 24 hours, 63.6 per cent., if within 36 hours, 87.5 per cent., and if delayed for 48 hours will only rarely succeed; or to give another example, than the results of surgical treatment of the intestine in typhoid fever, alas too seldom resorted to. To give an example kindly obtained for me by Dr. P. J. Cammidge: Out of a total number of 900 cases of typhoid fever occurring in St. Bartholomew's Hospital in the years 1895 to 1901 there were 102 deaths. Among the 900 cases were 38 of perforation, of which 34 died unoperated on, whereas of the 4 operated on 3 recovered. Could operation have been done in the remaining cases it would seem possible that 25 more lives might have been saved. In Professor Osler's clinic, out of 11 cases 5 were saved by operation. Intimately related to intestinal perforation is perforation of the gall-bladder in typhoid fever, of which 34 cases have been collected by Dr. Erdmann, of New York; of these 27 were not operated on and all died, but of the 7 which were operated on 4 recovered.

"As spontaneous recovery from perforation is extremely rare it is of the utmost importance that not only should we have an early recognition of the perforation, but also an immediate operation.

"Up to 1883 every case of intraperitoneal rupture of the bladder had died, but in that year the late Sir William MacCormac operated on and saved two lives; since that time there have been 54 operations recorded (according to Dr. Jones, Annals of Surgery, June, 1903), out of which 28 recovered, could these cases have been seen earlier, the saving of life would have been much greater, for in the cases that recovered there had only been an average interval of 25¼ hours between the accident and the operation, whereas in the cases that died the average interval had been 32 hours, and of the 26 deaths, 17 were due to peritoneal infection. Just as in gastric ulcer, the danger is increased with every hour of delay between the accident and operation; hence in case of doubt, exploration (which can be done through a very small incision, just sufficient to admit the finger) is safer than waiting, and experience shows that the aiding of the diagnosis by the injection of air or fluid into the bladder adds to the risk of general peritonitis by spreading infection over the whole abdomen.

"In injuries of the abdomen by penetrating wound, whether stab or bullet wounds, the resulting troubles are from infection, either directly through the instrument causing the injury or by perforation of one of the hollow viscera and escape into the peritoneal cavity of the septic contents; how much more rational it is to consider this as an infection and immediately to set about the removal of the poison and the repair of the damage, if it can be done under conditions favorable to success, than to treat it as peritonitis and rely on so-called antiphlogistic remedies. Few greater triumphs of scientific surgery can be shown than some of the remarkable cases of visceral injury, where stomach, bowel, liver, gall-bladder, and other viscera have been perforated, either by bullet or some other sharp instrument, and in which operation has been successfully performed, before infection has had time to occur.

"Appendicitis of the acute, perforating, or gangrenous type comes on so suddenly as often to constitute a peritoneal catastrophe, and in a proportion of cases terminates fatally in so rapid a manner that the diagnosis is made only with great difficulty, or not at all.

Such cases, when I was a student, went undiagnosed, and death was ascribed to peritonitis simply, a sufficient diagnosis in those days; and it was not till 1886 that we heard anything of this lethal malady, which though it has slain its tens of thousands is now, thanks mainly to the labors of Fitz, of Boston, who laid the foundation of our modern knowledge of the subject, brought under subjection in a very large percentage of cases.

"The disease is said to be on the increase, but I am not at all clear as to the truth of this, as there have been buried in our literary records for generations, fairly accurate accounts of dangerous inflammations occurring in the right iliac fossa and described vaguely as typhlitis, perityphlitis, paratyphlitis, etc., and both Copland and Burne in 1837 gave accurate descriptions of perforative appendicitis and its consequences.

**Hysterectomy for Myoma.**—"Although hysterectomy was unsuccessfully done by Heath in 1843, and successfully performed by Burnham in 1853, yet surgical progress was so slow that in 1883 a series of cases collected by Bigelow gave a mortality of 42 per cent., which was enough to condemn the operation, had it not been that Thomas Keith at that very time was doing brilliant work on the most serious cases, and establishing the operation on a sound basis. His mortality was 8 per cent., according to the late Greig Smith, who was himself operating with great success—barely a 5-per-cent. mortality. My own experience has been in 170 cases of operations for myoma, with a 5.2 per cent. mortality, this including all the earlier as well as the later operations, and including cases treated by the *serre-nocud* and by enucleation as well as by the more modern treatment of the pedicle and by panhysterectomy. The evolution of the operation of hysterectomy has been most interesting; just as the external treatment of the pedicle in ovariotomy gave the best results at first, so in hysterectomy the treatment by Koeberle's *serre-nocud* rendered the operation a justifiable one, and Dr. Bantock, Mr. Thornton, Lawson Tait, and others had considerable success by this means; but the difficulty of keeping the pedicle dry, the prolonged convalescence, and the subsequent liability to hernia led some surgeons to be discontented with it; yet I distinctly remember years ago when advocating the internal treatment of the pedicle at one of the societies, how some operators were very tardy to acknowledge the advantages of the operation introduced by Schroeder, and well on in the Nineties Greig Smith condemned it, stating that the mortality was double that of the extraperitoneal method. The latest statistics have been furnished by Mr. C. Bond, of Leicester, who recently reported 50 cases with 2 deaths—an excellent record.

**Biliary Surgery.**—"The surgery of the bile passages is one of the most interesting episodes in abdominal work, for although the first cholecystotomy was performed so far back as 1867 by Bobbs, of Indianapolis, it is only within recent years that surgery has come to be recognized as the treatment for gall-stones. I performed my first cholecystotomy in 1885, since which time I have operated nearly 600 times on the gall-bladder and bile ducts. When in 1889 I read a paper before the London Clinical Society, one of the leading London surgeons said to me, 'Wherever do you conjure your gall-bladder cases from; we never see them here?' I referred him to the medical wards and to the post-mortem room of any of the hospitals, with the result that within a short time he found many cases requiring relief. At first cholecystotomy only was practised, with the result that the ducts were often left obstructed and fistula necessarily followed. It was thought to be a bold venture when Lawson Tait crushed a stone in the common duct, a procedure which I followed with success on a number of occasions, until Courvoisier in 1891 showed it to be better to directly incise the common duct. Common-duct operations, as performed by the upward incision and rotation of the liver, which I introduced some time ago, are now as easy as an ordinary cholecystotomy used to be, for the improved method enables the whole of the biliary ducts to be brought near to the surface, and to be deliberately dealt with. Nothing could demonstrate this better than the results in my own practice in an experience of over 100 choledochotomies, for whereas in my first series before 1900 the rate of mortality was 23.8 per cent. in my last series it is only 1.5 per cent., and I have had a continuous series of 50 cases without a death; moreover, it must be borne in mind that nearly every one of these cases is not merely a successful operation but a life saved, for common-duct cholelithiasis associated with infective or suppurative cholangitis and deep jaundice is a mortal malady.

"Fortunately, gall-stones are usually easily diagnosed, the symptoms are classic and in the early stages before complications have supervened, cholithiasis is curable by surgical methods in 99 per cent. of cases, as I myself have demonstrated in a large series of operations; but if we wait for complications to supervene, and for the onset of jaundice and various infections, or until cancer has invaded the liver and gall-bladder, which it does ultimately in 50 per cent. of cases in which jaundice is present, then there will be a very different tale to tell.

"Even yet we do not get these cases always in time, and until the fact is grasped that medicine can, as a rule, only relieve and cannot cure cholithiasis we shall be continually having to operate in the presence of serious complications, endangering life, when operation is five to ten times more dangerous than if it had been undertaken at an earlier stage.

"The great reduction in mortality in gall-bladder surgery is due to an earlier diagnosis, a closer study of the pathogency of the disease, and infinitely greater care in operative technique. Much work remains to be done in this region, for it is a difficult and complex field, less accessible than many other regions of the abdomen, and often complicated by pancreatic trouble coexisting; but progress is steadily being made, and every year shows real advance tending towards perfection.

**Surgery of Liver.**—"The surgery of the liver was until recent years limited to the evacuation of abscesses and hydatids, and it is interesting to note the evolution of the various methods following closely one on the other; of emptying by trochar or aspirator; of opening by caustic or thermocautery; of incision *à deux temps;* and, lastly, of the method which we now generally adopt —hepatotomy, or direct incision of the organ after reaching the liver, either through the abdominal parietes, or, if necessary, through the thoracic wall—an operation the credit of which must be given to Lawson Tait, who published a first series of 10 cases between 1873 and 1882, all successful. Mr. Bryant, Mr. Knowsley Thornton, Mr. Godlee, myself, and others followed on the same lines. As showing the extent of this field of work I have operated directly on the liver for one disease or another nearly 100 times, this being exclusive of cases of jaundice dependent on gall-stones or pancreatic disease, for which I have operated on many more occasions.

"At first sight it would seem impracticable to remove a tumor of the liver but experience shows that although the liver tissue is friable and the capsule thin and not easily sutured, the bleeding is readily arrested by pressure, and it is possible to remove both simple and malignant tumors if localized and not too extensive.

Out of 9 operations for partial hepatectomy that I have performed, 8 have recovered, and in 2 cases where I removed a cancer of the gall-bladder and liver, the disease being proved microscopically, the patients are now in perfect health four years and three years respectively after operation.

"Dr. Keen, of Philadelphia, collected 20 cases of partial hepatectomy with only 2 deaths, and others have been performed since with equal success, so that the operation is one of real practical utility.

**Stomach Surgery.**—"The surgery of the stomach is still more recent than that of the gall-bladder, but unlike gall-bladder work, which was successful from the outset, the way to success in gastric operations has been paved with many failures, and only recently has the surgeon been able to show what can be done in this branch of the work. For instance, when gastrotomy was first performed by Sedillot and by those who followed him, it was nearly always fatal, the chief reason being that the patients were never handed over to the surgeon until nearly moribund; of such were my first 8 cases, of which 6 died; even up to 1890 the mortality was so great that the operation was seldom advised, yet it can now be done in so short a time and with so little disturbance that out of my last 24 cases all have recovered except 1, leading to considerable prolongation of life in the malignant and to saving of life in the simple cases. In the Seventies, any one with carcinoma of the stomach was at once given up as hopeless, and only in 1879 was the first attempt made by Péan to remove a malignant pylorus, the first successful operation being performed by Billroth in 1881, when the operation was looked on with as much disfavor as was the first attempted complete gastrectomy a few years ago by Connor in America, yet Schlatter's patient a little later lived fourteen months after complete gastrectomy, and I can point to a man in good health on whom I performed almost complete excision of the stomach two and a-half years ago, and to others now well who have had partial gastrectomy done. Professor Kocher's statistics in this branch of work are of great importance as showing that the radical operation may in some cases, if done thoroughly, prove curative.

**Gastric Ulcer.**—"Until quite recently gastric ulcer, except for one or two of its complications, has been considered to be a subject for medical treatment from first to last. The profession is, however, becoming awakened to the fact that it is not the trifling ailment it was once considered to be, and that it should from the first be taken seriously, for it is in the early stages that medical treatment can be employed to the best advantage, and in the later stages that general treatment is so often followed by relapse or by serious complications.

"Leube, one of the greatest medical authorities on the subject says that one-half or three-fourths of all cases will be cured by four or five weeks of treatment, but, if not better in that time, they will never be cured by medical treatment alone; and Einhorn says it is fatal directly and indirectly in 50 per cent. of cases when reliance is placed exclusively on medical treatment. It can be demonstrated that in the patients incurable by medical means surgery holds out a good hope of relief or cure in 95 per cent. of cases, as I have shown in an address recently given before the London Polyclinic. The subject is too large to enter minutely into, but from what I have stated now, and in other places have given in detail, it will be seen that in this as in other diseases of the stomach, modern surgery has very great triumphs to record.

**Pancreatitis.**—"The pancreas had practically received no attention from a surgical point of view up to Senn's classical experimental work in 1886, and even for some time after that the only interest centered around cysts, so that Greig Smith, writing in 1896, said, "The experience of the last ten years has added little to the work of Senn of Chicago." But what do we see to-day? That the subject is of such magnitude as to need a volume of considerable size to adequately deal with its pathology and surgical treatment. I myself have operated on nearly a hundred cases of diseases of the pancreas of various kinds. Acute pancreatitis is one of the most serious and fatal of diseases, often coming on with startling suddenness, and it is astonishing how it can have escaped the notice of pathologists until so recently. Fortunately surgery has been able to interfere beneficially in some of these cases, especially those ending in suppuration, and as our knowledge of the subject increases we shall be able to do more both in the way of prevention and cure. Chronic pancreatitis, though recognized from a pathological point of view, was practically unrecognized as a subject for surgical treatment until I drew attention in June, 1900, to the facts derived from an experience extending over some years, that many cases described as cancer of the head of the pancreas and leading to chronic jaundice, which ended fatally, were really cases of chronic pancreatitis that could be cured by draining the pancreatic duct indirectly through the bile passages; this has led to great success in the treatment of a class of cases previously treated as hopeless. The treatment of cysts is most successful, and it is now well established that in drainage we may reasonably expect to cure or materially relieve in a very large proportion (probably 93 to 95 per cent.) of cases.

**Tuberculous Disease.**—"The advances in the pathology and treatment of phthisis since the discovery of the tubercle bacillus have become public knowledge, but I do not think it is quite realized how enormous the saving of life has been; for, while in 1838, 38 persons in 10,000 died of phthisis, the proportion is now but 13 in 10,0000. Now can we show anything like this in surgical tuberculosis? I think we can, since preventive medicine of course applies equally here; and there can be no doubt that the early recognition of joint and bone disease has led to more rational therapeusis and a great saving of life and limb. To-day, however, I need only consider tuberculosis as it concerns the abdomen; and just as we saw that so-called acute peritonitis may be better described as an acute peritoneal infection, so, in the case of chronic tuberculous peritonitis, we should do better to term it tuberculous infection of the peritoneum, for it is generally a secondary infection; and frequently, as can be proved from actual cases, may be treated in an early stage by removal of the cause, whether that be a tuberculous appendix, a tuberculous pyosalpinx or ovary, a tuberculous mass of intestine or mesenteric glands.

"Although Spencer Wells some years previously, accidentally discovered that an extensive abdominal tuberculosis was cured by drainage of the peritoneum, it was not until 1884 that Koenig (*Centralblatt für Chirurgie*, 1884 and 1890) planned the operation which has had such good results, and has led to so many successes.

"What we must do in the future is to prevent these diseases if we can, by avoiding the distribution of tubercle bacilli in the air and in our food; or failing that, we must if possible catch cases at an earlier stage, and remove the primary focus, so as to prevent the general invasion of the peritoneum to which I have just referred. If, however, we are only consulted when the disease is so far advanced that medical treatment can do no more good, drainage of the abdomen by a simple and short operation may bring about recovery in a remark-

able manner, and I have seen patients reduced to the last extremity of weakness, where the mesentery was standing stiff with tubercle, and the abdomen was swollen to an enormous size, to recover completely and be thoroughly restored to perfect health from a condition apparently completely hopeless.

"**The Surgery of the Intestines** provides the most varied and difficult field of work in the abdomen, and as the ordinary methods adopted in general surgery here need modification, the evolution of intestinal surgery has been accompanied by infinite variety in detail.

"The interrupted suture at first employed occupied so much time in application that many modifications were soon introduced, and in 1885 Mr. Bishop showed there were no fewer than thirty-three distinct methods of enterorrhaphy, and since probably as many more have ben introduced.

"In 1887, Senn's plates were employed to facilitate the process of intestinal anastomosis, and I remember what a great impetus was given to the surgery of the intestinal canal by Dr. Senn's very able paper and demonstration at the International Medical Congress in Copenhagen. In 1892, being dissatisfied with the methods then in vogue, I invented a decalcified bone bobbin shaped like a cotton reel, which would form a temporary splint around which to apply two continuous sutures, one to the serous and another to the mucous margin of the new openings; which method has proved most useful, and I feel sure has ministered to whatever success I have had in this line of work.

"In 1892 Dr. Murphy, of Chicago, invented his well-known metal button, which, since it is employed without previous application of sutures, can be used very quickly, and by its distinguished inventor as well as in the hands of other surgeons it has been adopted with great success. The chief disadvantages it presents are (1) that it is necessarily associated with sloughing of the compressed and coapted ends of the bowel; (2) that a foreign body is left in the canal which sometimes produces ulceration and other troubles; and (3) that the opening has been found in some cases to contract and necessitate a further operation.

"It is astonishing what large portions of the intestinal tract may be taken away with safety; for instance, Mr. Barker removed 5½ ft. of damaged bowel with success in a case of strangulated gangrenous hernia, and I have on several occasions removed part of the ileum, the cecum, the ascending and part of the transverse colon with recovery of the patient.

"In the first number of the International Archives of Surgery is the description of a case in which Dr. Roswell Park removed 8 ft. 9 in. of gangrenous small intestine, the patient being well a year later; and in the same paper reference is made to 17 other cases in which over 6 ft. of bowel had been excised with recovery in 14; in one of these cases no less than 11 ft. were removed.

"In 1884 colotomy had the enormous mortality of 31.6 per cent. for the lumbar and 53.1 per cent. for the inguinal operation, as shown by Dr. W. R. Batt, who collected the records of 351 cases; in 1889, under improved technic, the inguinal operation was reintroduced by Mr. Allingham, with the result that the mortality was diminished in a short time to under 10 per cent., even including cases of acute obstruction, though excluding the acute cases the mortality is under 5 per cent. Looking to the future, it seems highly probable that colotomy will be largely replaced by the removal of the disease, for it has been clearly proved that there is no part of the lower bowel which cannot be safely excised if taken sufficiently early, and I can point to a number of patients living in comfort from whom I removed rectal cancer years ago; in one the patient being in good health ten years after. Mr. Watson Cheyne estimates the mortality of excision of the rectum at from 5 to 10 per cent., and refers to Kocher's statistics in which 28 per cent. of cases remained well from three to sixteen years after proctectomy.

"For the rational treatment of intestinal obstruction we owe much, first to the anatomical researches of Sir Frederick Treves, and secondly to his admirable work on the pathology and surgery of the subject.

"At the present day the differential diagnosis has been so well worked out, and the technic of operative work so much improved, that no physician or surgeon long delays resorting to operation if relief be not soon obtained, and the results as shown by numerous reports, amply justify the change.

**Hernia.**—"When I was a student much time was spent and great expense incurred both by patients and hospitals in the fitting of trusses to enable those crippled by rupture to go about with any degree of safety or comfort and many of those patients ultimately lost their lives through strangulated hernia, the operation for which at one time as shown by Mr. Barker, had the huge mortality of 53.1 per cent., and even yet, according to that surgeon, has in hospital practice the high rate of 22.2 per cent. My own experience does not bear out this high mortality, though I find it, as one would expect, to vary in hospitals and in private patients. Taking all my cases of strangulated hernia from 1880 to 1903, both in hospital and in private, the mortality has been 13.5 per cent., but while the private cases, for the most part operated on without loss of time, show only a mortality of 5 per cent. since 1890, the hospital cases seen at a later stage, show the all-round mortality of 14.2 per cent., and I thoroughly agree with Mr. Barker that cases seen when the bowel has become seriously changed will stand a much better chance of recovery if the damaged gut is removed by a free enterectomy of the proximal end.

"What we want, however, to impress on the public, is to have the radical cure performed early, when it is practically devoid of risk, as shown by the following statistics. In the Johns Hopkins Hospital there was only 1 death in 459 operations. In Carle's clinic in Rome, 2 deaths in 1,400 operations, in the Vienna clinic 3 in 804, and in Dr. W. B. Coley's 1,075 cases only 2 deaths, all of which when massed together give a mortality of about one-fifth per cent. But where the radical cure has not been done and strangulation unfortunately occurs, it ought to be more fully grasped that no time should be lost in taxis, but that operation should be performed without delay, when it can be done with a risk of not more than 5 per cent. and radical cure can at the same time be performed.

"**Ectopic Gestation** until recently constituted a dark chapter in medicine; it was altogether misunderstood both as to cause, pathology, symptoms, and treatment, and hundreds of lives were lost annually which are now saved by timely surgical intervention. To the genius of Lawson Tait, who utilized the post-mortem experience of Bernutz and Goupil published in 1886, and the clinical observations of J. S. Parry, we owe the successful treatment of this otherwise fatal disease. His work on this subject alone should be sufficient to establish a claim for him to be placed among the great benefactors of science and of humanity.

"As showing the success of his treatment from the first, up to 1887 he had operated 35 times for ruptured tubal pregnancy with only 2 deaths, and in my valedictory address at the termination of office as President of the British Gynecological Society in 1898 I was able to report, following on the same lines, 23 operations

for ectopic gestation with 1 death. The subject has received much attention at the hands of Professor J. W. Taylor, of Birmingham, Mr. Bland-Sutton, and others, but only recently has it been distinctly proved by 4 undoubted cases, 1 of which came under my care, that ovarian gestation is a possibility.

**The Surgery of the Kidneys and Ureters.**—"Although the dawn of renal surgery dates from August 2, 1869, when Simon of Heidelberg deliberately performed nephrectomy, the first successful operation in England was done by a member of your Council, my respected colleague, Mr. T. R. Jessop, an operation which I had the privilege of witnessing. Sir Thomas Smith advocated nephrotomy in 1869 before Simon's operation, but it was not until 1870 that Mr. Bryant first performed the operation and until 1880 that Mr. Henry Morris applied it to the removal of a calculus. As showing the advances that followed, the last named surgeon was in 1898 able to report 34 nephro-lithotomies with 33 recoveries, showing the invalidity of the objection which had before 1880 been urged against the proposal to operate on a kidney not already converted into a mere abscess sac; and proving that the conservation of the kidney by removal of the disease was infinitely better than the sacrifice of the organ, which was at one time advocated. The next advance was due to Hahn, who in 1881 described two cases in which he had performed the operation of nephropexy for the fixation of movable kidney, a procedure which in proper cases confers great benefit on a class of patients who previously had to bear their troubles until the movable organs were often converted into large fluid cysts owing to intermittent kinking of the ureters. By utilizing the partly stripped capsule and the posterior incision of Edebohls, I have been gratified with the results, both immediate and remote, of the operation, which with little or no risk, in properly selected cases, has been the means of restoring many invalids to a state of health and comfort.

"The most recent advance in renal surgery has been in the treatment of chronic nephritis of Bright's disease, which was first drawn attention to by my friend Mr. Reginald Harrison, who recommended the renal puncture or incision in certain cases of chronic albuminuria; but to Dr. Edebohls, of New York, must be given the credit of adopting an original operation for the treatment of Bright's disease. He in 1898 deliberately exposed both kidneys, stripped their capsule, and fixed them in position, in a young woman of twenty-six. Frequent examinations during the five years showed in every instance normal conditions, and the patient has recently married and is well. In March of this year Dr. Edebohls reported 51 cases of renal decapsulation, and in 47 of these cases both kidneys were operated on at the same time. Out of this large number, 22 are said to be improving from three to fifteen months after operation.

"As yet it is too early to pronounce a definite opinion on the procedure, but it is an undoubted fact that recapsulation does effect some improvement in this serious malady, and it may possibly prove effectual in saving life in those terrible cases where suppression of urine comes on after some trifling operation, such as catheterism, or after a chill, or in scarlatina; just as surgery has effectually stepped in and saved life where suppression was due to obstruction of both ureters. We may certainly go so far as to say that no patient ought to be allowed to die from suppression of urine without the surgical question being considered.

**Immunity.**—"In future it seems assured that many of those infections will be dealt with by the method of immunization; and it seems not at all improbable that, even if such diseases cannot be prevented, the necessity for operation may in some be staved off, while in others the operative results may be materially improved, and the postoperative anxieties lessened by protective inoculation before operation.

"Of the treatment of streptococcus infection, such as erysipelas and other diffuse inflammations, by the antistreptococcus serum we can probably all point to some excellent as well as to other uncertain results; but as improvement in the preparation of the antitoxin occurs, and as our knowledge of when and how to use it is increased, we shall be able to calculate on more certain results. At the present time surgeons are finding the injection of the serum of service in immunizing before operating in certain regions, such as the tongue, mouth, throat, and rectum, where asepsis cannot be secured with certainty.

"Dr. A. E. Wright's researches with regard to localized staphylococcus infection, as in boils, acne, and sycosis, have shown that in all these cases there is a defective power of phagocytosis with respect to the staphylococcus, as well as invasion by that organism. The inoculation of a staphylococcus vaccine has the effect in a considerable proportion of cases of immunizing the patient against the special organism, and in the Lancet for March 26, 1902, Dr. Wright has given his experience of the remarkable results he has obtained in these well-known and troublesome diseases of the skin and hair follicles.

"These researches on the localized cutaneous invasions of staphylococci have paved the way for further therapeutic applications in connection with wounds and open ulcers.

"It seems not improbable, in the early future, that in all inflammations, whether of the respiratory tracts or the pleura, of the brain or the meninges, of the uterus or its appendages, of the middle ear and its sinuses, of the abdomen and its contained viscera, as well as of the joints and bones, that the services of a skilled pathologist will be required, who will by a blood examination or otherwise determine the organism or organisms causing the infection, when the appropriate serum or vaccine will be immediately employed, so as to arrest the inflammatory process, or in case of the disease having advanced too far for arrest, to limit its extension, and by a process of immunization to prepare the patient for operation, should such be called for.

"Gentlemen, I have tried to show that the advances in treatment during the past third of a century have been commensurate with our increased knowledge of disease, and simply on account of time have I limited myself in a great measure to diseases of the abdominal cavity.

"I have tried to show what a close connection exists between the science and art of our profession, and how very necessary it is, if we are to continue our march of progress, that experimental research should not only be untrammeled by factions and unreasoning opposition, but that it should receive greater recognition, encouragement, and support at the hands of the public.

"I have tried to forecast the future, and to show that while surgery has still great strides to make and many difficulties to conquer, such progress will be in a great measure intimately bound up with the work of the physician, the pathologist, and the bacteriologist, and I think the time will come when preventive measures such as I have portrayed will save much operative work, and when it will be thought a greater triumph to prevent than to cure disease.

"We can see that methods and policies which were sufficient years ago are totally inadequate to-day. We may modify but we can not prevent the world's advance, and while times change men change with them. The

medical profession is imbued with a spirit that half a century ago was undreamed of. Not only have apparently unsurmountable difficulties been overcome, but habits of thought have been attained which have made such achievements possible, and a scientific attitude of mind has become characteristic of our profession, as it has of the leaders in every branch of the world's progress.

"In becoming more scientific, it is a mistake to suppose that the medical profession has lost touch with higher beliefs. As Lord Kelvin has so happily stated it lately, 'Science positively affirms creative power. We only know God in His works, but we are absolutely forced by science to believe with perfect confidence in a directive power, in an influence other than physical, or dynamical, or electrical force.' There is no harm in free thinking, for if we think strongly enough we are forced by science to the belief in a higher power, which is the foundation of all religion."

*(To be Continued.)*

## BOOK REVIEWS.

Transactions of the American Ophthalmological Society. Thirty-eighth Annual Meeting, New London, Conn. 1902. Vol. IX. Pt. 3. Hartford, Conn. Published by the Society.

It is but faint praise to state that these Transactions increase in value from year to year. The Society records here the loss of one of its most distinguished founders in the person of Dr. Henry D. Noyes, whose portrait is the frontispiece and whose well-written eulogy is the foreword of the book. Glaucoma is again carefully studied. Many cases of carcinoma are reported. A study of changes caused by injections of pure cultures of *Bacillus typhosus* into the anterior chamber of rabbits' eyes is carefully recorded. There is a study of the diffusion circle in correction of ametropia. Cases of tobacco amblyopia, methyl alcohol debauch and fatal cavernous sinus thrombosis from grip with its important treatment, are reported; also a careful study of "ossification of the choroid." Tests for color-vision are reconsidered. Finally a careful study is made of primary insertions of the ocular muscles. The whole is a volume of great value.

Uterine and Tubal Gestation. By Samuel Wyllis Bandler, M.D., Instructor in Gynecology, New York Post-Graduate Medical School. Wm. Wood & Co., New York.

This little volume is but an elaboration of articles on the same subjects published in The American Journal of Obstetrics and Gynecology.

In a way it is decidedly unique, in that it deals with the subjects almost entirely from the laboratory point of view, giving us the true scientific aspect of the conditions which occur in the tissues of the maternal generative organism during both tubal and uterine gestation. It is most unfortunate, however, that such a book will not prove to be of much service to the medical profession at large, as it is too technical and requires a too intimate knowledge of histology, embryology and pathology for the average practitioner to appreciate what the author has to say.

The third portion of the book is devoted to the histology of that most interesting condition known as chorio-epithelioma. The author suggests that the origin of the metastases may be explained by the fact that fetal cells are carried into the maternal circulation and are deposited here and there to become foci of proliferative cell agglomerations of the fetal type. But this does not seem satisfactory, for if such were the case we might with reason expect the metastases of liver, kidney or cells from any fetal organ to do the same thing.

Dr. Bandler's book deserves commendation from the thoroughness and clearness of its subject-matter and is undoubtedly a valuable treatise of its kind.

A Text-Book of Chemistry for Students of Medicine, Pharmacy, and Dentistry. By Edward Curtis Hill, M.D., Professor of Chemistry and Toxicology in the Denver and Gross College of Medicine, University of Denver. F. A. Davis Company, Philadelphia.

While a work of the more or less conventional type this volume of Dr. Hill's has much to commend it, particularly to students of pharmacy and of medicine.

The information is reliable, well arranged and well chosen; there are excellent chapters on drug incompatibility in prescriptions and on adulterations and sophistications in food—chapters that can not fail to be of immense interest to all students.

We find very little of the newer physical chemistry of Ostwald, Nernst and others, much of which might have been incorporated to advantage, but for practical purposes the book is in many senses admirably adapted for the needs of the students for whom it was prepared.

Diseases of the Heart and Arterial System. Designed to be a Practical Presentation for the Use of Students and Practitioners of Medicine. By Robert H. Babcock, A.M., M.D., Professor of Clinical Medicine and Diseases of the Chest, College of Physicians and Surgeons, Chicago. D. Appleton & Co., New York and London.

In many ways this is a remarkable book. It not only reflects great credit on the author for his grit in overcoming what to most men would have proved insuperable obstacles, but he has moreover given us almost the first good authoritative work on diseases of the heart and blood-vessels by an American author.

There are 853 pages of closely written text with over one hundred illustrations, most of which are admirable from both the pedagogic and artistic standpoints. The book-making is in accord with the publishers' well-recognized sterling quality.

In its general scope and mode of handling the work does not differ very widely from other well-recognized standards. Foreign and home authors are widely quoted, but nevertheless the work has a distinct individuality.

We feel that we can recognize in this work an entirely new note of a superior character, a refinement much above the average of the descriptions of sound phenomena that stamp it as unique. The signs gained by the organs of hearing are here given with a completeness and finesse that is not found elsewhere. The author's blindness has made the medical world profit thereby, for special analysis of sound phenomena has undoubtedly given him an acuity of this sense possessed by few others.

Another point of advantage is the plain practical and straightforward character of the author's descriptions and his lengthy consideration of the therapeutic side of the problems presented. Treatment is full and very satisfactory.

We commend to our readers this work of Babcock's as a very desirable work for both the specialist and the practitioner, and wish the author a most hearty welcome for his admirable literary endeavor.

## ORIGINAL ARTICLES.

### CARDIOPTOSIS.

BY ALBERT ABRAMS, A.M., M.D.,

OF SAN FRANCISCO.

THE downward falling of the heart, which this term implies, is a condition to which only inadvertent reference is made in medical literature, notwithstanding the fact that the personal observations of the writer show it to be more than a mere phenomenon. In this connection, congenital anomalies, such as transpositio cordis and ectopia cordis, the result of fissural malformation of the anterior thoracic and abdominal wall will be wholly disregarded. The recent literature on cardioptosis is practically limited to the observations of Rummo[1] and Ferrannini.[2] The former unfortunately includes under the designation, cardioptosis, luxations of the heart without specifically limiting the term to an essential ptosis of the heart. Ferrannini, while recognizing ptosis of the heart as an essential condition, associates it with anomalies in the form of the body. He contravenes the current assumption, that downward displacement of the heart is the result of mechanical influences which force it downward such as tumors, pleural effusions, etc. In his four reported cases, the cardiac dulness was of normal extent, but both the upper and lower borders were lower than normal and there was decided epigastric pulsation. In all, there was mitral stenosis. The patients showed abnormalities of growth and other signs of imperfect development of the skeleton and large vessels and he believes that cardioptosis was caused by congenital imperfections in the vascular system and by the mitral stenosis which he considers to have been congenital. The loss of elasticity in the vessel walls and the enlargement of the heart allowed of the dropping of the organ downward. My own observations refer to individuals in whom no cardiac anomaly was present beyond malposition of the organ and when murmurs were demonstrable, they were accidental. The cases referred to permit of the following etiological classification: (1) Voluntary cardioptosis; (2) cardioptosis associated with ptoses of the abdominal viscera; (3) cardioptosis of accommodation; (4) primary essential cardioptosis, with no other cause, beyond a supposititious one, of impaired tonicity of the large blood-vessels supporting the heart.

The situs of the heart is maintained by pulmonary suction. The lungs occupy all of the chest excluding the area occupied by the mediastana. To occupy the thoracic space, the lungs must undergo considerable stretching and this is made possible by the large amount of elastic fibers which enter into their histological composition. For this reason, the lungs show a constant tendency to contract and this inclination is augmented during inspiration but the atmospheric pressure within the lungs overcomes this tendency and as a consequence the lungs are kept in relatively close contact with the chest walls and the contiguous intrathoracic structures. The lungs thus exercise a negative pressure or suction on the structures referred to, which is called pulmonary suction. The presence of air or fluid in the pleural cavity of one side diminishes the pulmonary suction on that side and the greater suction of the unaffected side will cause the heart to be drawn to the latter side. Displacement of the diaphragm is a late phenomenon of gas or fluid in the pleural cavity and only occurs in the presence of large accumulations of fluid or gas. Another factor which influences the situs of the viscus is the position of the diaphragm to the central tendon of which the pericardium is attached. Every descent of the central tendon of the diaphragm means a downward movement of the heart. Physiologists have taught that the central tendon is capable of only limited movement and Campbell[3], asserts, that, when the pulsating heart is felt in the epigastrium after deep inspiration, it is not due to an actual descent of the heart but to a lifting upward of the thoracic cage over that organ. The Roentgen rays, however, have despoiled the physiologist of many accepted facts. The rays show that the heart descends during inspiration and ascends during expiration. During the former phase of respiration, the silhouette of the heart becomes more defined, the transverse diameter diminishes and the heart inclines slightly towards the right. During inspiration, the cardiac pulsations show less amplitude than in expiration, a fact which may be referred to the stretching of the pericardium during inspiration. During expiration, the heart rests on the diaphragm with its long axis at an angle with the median line of the body but with each inspiration, the heart becomes more vertical with the long axis less inclined toward the horizontal. Measurements of the transverse diameter of the heart show it to be less during inspiration than during expiration. During deep inspiration, a clearly defined space may be seen between the heart and the diaphragm for in this phase of respiration, the heart is supported by the blood-vessels and does not rest on the diaphragm.

*Etiology.*—There are other factors beyond those mentioned in my etiological classification which induce cardioptosis. Some of these factors are: (1) Increased size and weight of the heart; (2) aneurisms and new growths which displace the heart downward; (3) adhesions, pleural or pericardial. None of these factors,

however, were concerned in the cases which have come under my observation.

*Voluntary Cardioptosis.*—The most pronounced case of this kind which ever came under my observation[4] was that of an individual who could produce voluntary dislocation of the heart, stomach and kidney. He had developed phenomenal control of his diaphragm. With the gastrodiaphane, one could observe with what ease the individual in question could shift his stomach about. He could dislocate his stomach downward to a point on a level with the crests of the ilia and then by a supreme effort, he could draw his stomach upward until it could no longer be seen. He could develop a phantom tumor at will by buccal insufflation of the stomach, relaxation of the recti muscles, forcible contraction of the diaphragm and forward arching of the vertebral column. His apex beat, which was felt in the fifth, could be made to descend to the seventh intercostal space and it was maintained in the latter situation until his control of the diaphragm was relinquished.

*Cardioptosis, a Participating Condition in Splanchnoptosis.*—Cardioptosis, associated with Glénard's disease, is, in my experience, rarely associated with symptoms referable to the heart beyond the objective sign of misplacement of the organ. The position of the diaphragm, and with it the heart, is greatly influenced by intra-abdominal tension. In its passive state, the diaphragm lies high owing to the negative pressure on its upper and the positive pressure on its under surface. Two factors enter into play in maintaining intra-abdominal tension, viz.: pressure of the atmosphere on the yielding abdominal parietes and contraction of the abdominal muscles. Intra-abdominal tension varies from hour to hour and is much increased by augmented intragastric and intestinal pressure. I have already shown[5] the influence of a dilated stomach and distended colon on the position of the heart by artificial insufflation of the stomach and colon while the Roentgen rays were traversing the chest. The tonicity of the abdominal muscles is an essential factor in maintaining the normal position of the underlying viscera. Flaccid abdominal walls diminish intra-abdominal tension and conduce to ptosis of the abdominal organs, descent of the diaphragm and prolapse of the heart.

*Cardioptosis of Accommodation.*—We have long recognized the almost intelligent function of muscles whether displayed in fixing a diseased joint or spine, or in protecting an inflamed serous membrane. Now the midriff will become fixed in the deepest inspiration when, if for any reason, there is any encroachment on the respiratory area in the upper thorax. With this descent of the diaphragm, there is also a downward luxation of the heart which I have referred to elsewhere[6] as the dislocation of accommodation, it being a mere act of compensation on the part of Nature to augment the area of respiration which has been compromised by the presence of an aneurism or tumor. It is usually taught that descent of the heart in aneurism and in an intrathoracic neoplasm is purely of mechanical genesis but cardioptosis occurring early in these conditions, at a time when the mechanical element can be of no consequence suggests descent of the diaphragm as the only plausible explanation. In old age, the accommodation of dislocation is commonly present and the low position of the diaphragm and heart is a mere accommodation phenomenon to compensate for the increased length of the aorta. If we make firm compression of the upper thorax of a child one may note the immediate descent of the heart. I have observed dislocation of accommodation in thoracic aneurism if the latter is unaccompanied by aortitis.

In health during deep inspiration, there is usually a free space between the heart and diaphragm, and the heart does not rest on the latter but is supported by the blood-vessels. In aortitis and aneurism associated with anginous signs, the diaphragm lies high, as if to support the heart and diminish traction on the blood-vessels. This intelligent display of muscle instinct which is in part voluntary causes the heart to lie high if in aneurism pain predominates and to lie low, if dyspnea is the predominant symptom.

*Primary Essential Cardioptosis.*—The majority of cases observed by the writer belong to this category. There was no associated condition present to account for the cardiac ptosis beyond a relaxation of the arterial system and the writer is constrained to refer its genesis to a hypotonicity of the large blood-vessels which support the heart. Vascular hypoplasia is an almost constant condition in chlorisis and is often encountered in other conditions, notably in persons of tuberculous habit. There is no reason to believe that this congenital defect of development is ever wholly corrected and it may persist throughout life. Associated with this hypoplasia is a pronounced elasticity of the blood-vessels so that the aorta may be stretched like a rubber band. The pathologist often has an opportunity to observe the elasticity or non-elasticity of the arteries at a necropsy. Atheromatous arteries appear long after removal from the body because they are no longer endowed with elasticity, whereas elastic arteries appear shorter owing to their retractility. In three of my cases only could I make out a distinct history of chlorosis although at the time of my examination, hemanalysis demonstrated nothing characteristic of that affection.

*Symptomatology.*—Here reference will only be made to the cases of primary essential cardioptosis which have come under my observation. The signs are subjective and objective. The tableau of subjective symptoms is by no means characteristic. Very often cardioptosis may be present without subjective symptoms and the condition is only observed accidentally. In other instances a feeling of weight or oppression is experienced in the lower chest which is referred by the patient to the lower sternal region or epigastrium. This symptom is associated with epigastric pulsation and dyspnea. The dyspnea is very

much intensified by exertion. One of my patients, a physician, tells me that when he is compelled to lean forward to examine a patient in bed, his dyspnea becomes so pronounced that he cannot continue his examination. Even as a child, he noticed this dyspnea upon exertion, but of late years the dyspnea has become so intensified that he is almost compelled to give up the practice of his profession. Some patients show a preference for certain postures in bed but this manifestation is too inconstant to be of any value in diagnosis. Objectively, percussion is too indefinite to permit of accurate delimitation of the cardiac boundaries: the upper border of cardiac dulness, superficial and deep will be found to be lower than normal. The apex beat is with difficulty palpated and in lieu of the punctated beat a diffuse one is felt. Auscultation may or may not elicit cardiac murmurs and if present, they are greatly influenced by posture—a certain posture will bring them in evidence, whereas another posture will cause their evanescence. The murmurs are probably accidental and dependent on the malposition of the heart.

The pulse suggests diminished tension of the arterial wall: it is soft, readily compressible and its dicrotic character is clearly brought out in the sphygmogram.

The pathognomonic signs of cardioptosis are elicited by skiascopy. No description nor diagram can adequately describe the characteristic picture of cardioptosis. This can only be appreciated after a thorough acquaintance with the normal heart and its respiratory and postural mobility. The normal heart during deep inspiration is practically vertical and between the heart and the diaphragm there is usually a well-defined space. During expiration the long axis of the heart describes an angle with the median line of the body but this is not appreciable; to the tyro it appears as if the heart were sunk more deeply into the diaphragm; the upper part of the viscus still maintaining its vertical position.

In cardioptosis, the long axis of the heart appears to be practically parallel with the surface of the diaphragm; the boundaries are poorly defined and deep inspiration does not bring into evidence the clearly defined space between the heart and the diaphragm. This posture of the heart could be assumed if the midriff were abnormally high as in abdominal distention, yet, if the long axis of the heart were measured, it would be found by describing the distance of the axis on the chest wall, that it would extend higher in the thorax than would a normal heart. The highest anatomic point of the heart is represented by the left auricle which is at the lower border of the sternal insertion of the second rib, its lowest point is at the upper border of the sixth costal cartilage or in the fifth intercostal space just within the mammary line. Measurement of the long axis of the heart in cardioptosis would show that the heart lies lower than normal. The site of the normal heart is influenced by respiration and attitude. In cardioptosis there is little or no respiratory or attitudinal dislocation. Reference has already been made to the changes assumed by the heart during respiration. My measurements of attitudinal dislocation show that in the left lateral posture, the heart moves on an average of 2.6 to the left and 1.1 cm. upward; in the right lateral posture, 1.5 cm. to the right and 0.5 cm. upward. As a rule, attitudinal dislocation was less evident in children than in adults and less marked in obese individuals than in lean ones.

*Treatment.*—This can be dismissed in a word. I have found nothing of avail in the treatment of my cases beyond the wearing of good fitting abdominal support with pressure exerted in the upper abdomen. In cardioptosis associated with Glénard's disease, exercises having for their object strengthening of the abdominal muscles and the diaphragm often yield excellent results coupled with massage, faradization and hydrotherapeutic procedures. I have seen no results from medication, although digitalis would seem to be theoretically advisable in cardioptosis of the primary essential variety.

## MANAGEMENT OF BREECH PRESENTATIONS.

BY E. M. THOMAS, M.D.,
OF GEORGETOWN, TEXAS.

IN the management of breech presentations the attitude of the accoucheur during delivery, so long as there is no immediate danger to the child or mother, should be one of watchful observation. As a rule, the results to the child are unquestionably more favorable if nature does her work unaided, but should there be any faltering in the natural forces the physician should be in readiness to avert by prompt interference the perils which, in pelvic presentations, are associated with delay.

Pains should be taken to preserve the membranes until dilatation is complete, therefore, unnecessary examinations should be avoided: the patient should be placed upon her side and cautioned not to strain, and after the rupture of the membranes, it is best for the expulsion of the trunk to take place slowly, but when the hips appear at the vulva, the attending physician should be ready to extract at once in case of emergency. The patient should be placed across the bed with hips well over the edge of the bed, and she should be instructed to bear down with the pains.

The question of anesthesia is not always easy to decide. It is very useful in unruly patients, but it sometimes lessens the pains, and besides, you lose the very beneficial cooperation of an intelligent patient, which is a drawback to its use. The rectum and bladder should both be emptied. The operator should have at hand in case of need,

forceps, a soft fillet, warm napkins, hot and cold water.

The operation is divisible into three acts: (1) Extraction of the trunk as far as the shoulder; (2) extraction of the arms and shoulders; (3) extraction of the head.

The extraction of the trunk should take place slowly, and tractions should be made during the pains only, and it is desirable that the uterus be closely retracted upon the child during the entire period of its expulsion. When this does not occur the arms are liable to be pushed upward to the sides of the child's head, the chin to become extended, and the delivery of the head would become very difficult; hemorrhage, too, is more likely to follow hasty delivery than where the uterus has had time to pass into a state of complete retraction; therefore firm pressure should be made upon the uterus through the abdominal walls, so as to maintain firm contraction upon the head of the fetus. Traction should be made downward and backward in the direction of the superior strait, until the breech comes in contact with the floor of the pelvis.

When the breech alone presents, with both extremities reflected upward parallel to the anterior surface of the child, spontaneous delivery is sometimes prevented by the fact that the extended limbs act as splints which interfere with the lateral fluxion of the trunk, and, consequently, with its accommodations to the curve of the parturient canal. If in pure breech presentations obstetrical aid becomes necessary, the operator is embarrassed by the absence of a natural handle, by means of which extraction can be effected; but, if the child is of ordinary size and the resistance at the pelvic floor is not too great, the expulsion of the child may sometimes be effected by graduated pressure upon the fundus of the uterus. Should this measure fail, manual extraction should be attempted. The index finger should be inserted into the fold of the anterior groin, and traction made directly downward. If the breech is low, both index fingers may be used, one in each groin, but should manual extraction fail (which is very likely to happen, especially in primipara), then instrumental aid becomes necessary. The choice consists of the forceps, the fillet, the blunt hook, and, when the child is dead, the cephalotribe in the order given.

But the forceps, being designed to fit the fetal head, when applied to the breech to which its curves are not adapted, is liable to slip off when traction is made, thus endangering the maternal soft parts and if, with the view to prevent slipping, the handles are compressed firmly, it has been urged that fracture of the femur may occur, or that the circulation of the cord may be cut off by the pressure, or that fatal injuries may be inflicted upon the fetus by the pressure of the points of the forceps upon the abdominal viscera, but with the axis traction forceps of Tarnier, some of the objections have been very materially diminished. The forceps should never be used until the child has passed the superior strait, and some authors advise, not until it is well down upon the floor of the pelvis, and in the use of the forceps there should be no exhibition of strength. The tractions are most effective if made during the pains, and gradual and intermittent tractions will soften and dilate the material soft parts better than continual hard pulling. They should be aided by simultaneous pressure upon the fundus of the uterus.

If the forceps fail, or if, owing to the non-engagement of the breech, they are contra-indicated and an extremity cannot be brought down without the employment of force, the next best thing is the fillet. The objections urged to its use are that the fillet might become twisted or, in getting wet, it might form an uneven band, which, even with care, might cut into the tissues of the child, or that in some cases it causes partial extension of the extremities, and as a consequence might slip forward upon the thigh and, in making traction, cause fracture of the thigh bone.

But Ollivier suggests that this extension can be prevented by passing the finger into the rectum of the mother and pressing the breech forward as tractions are made.

The fillet should be passed over the anterior thigh, the tractions should be of moderate force and should be made only during the pains, and should be sustained by external pressure over the fundus uteri. The fillet can be made of any strong material, but caution should be used in preventing folds, as they are apt to cut into the soft tissues of the child. In the absence of other appliances, or should failure attend the measures already described it is well to remember that the blunt hook owes its sinister reputation not so much to its defects as to proper caution in its use, it will not break the femur if adjusted in the groin; it will not produce serious contusions if the blunt end is carefully guarded by the fingers, and injuries to the maternal tissues can only occur where leverage movements are made. Steady downward tractions made with moderate force, with a hand in the vagina to guard the point of the instrument and to give warning of commencing extension of the thigh, will, as a rule, suffice to prevent accident.

No instrument will seize the breech so securely as the cephalotribe. If, therefore, the child is known to be dead, the cephalotribe screwed tightly to the breech can be trusted to act as a reliable tractor.

*Management of the Cord.*—As soon as the cord has passed out of the vagina, traction upon the navel should be avoided, by gently pulling the cord downward into one of the recesses until some resistance is experienced. Sometimes the cord is found passed between the child's legs and up over its back, in which case traction should be made upon the placental extremity, and an attempt made to slip the loop over the posterior thigh. But if this fails, and the cord is wound around the child's body, two ligatures should be applied and the cord divided between, and every

effort be made to deliver the child as speedily as possible.

*Liberation of the Arms.*—After providing for the safety of the cord, the pelvis of the child should be seized with both hands and traction made in a downward direction until the shoulder blades make their appearance. Then no time should be lost in liberating the arms. If they are folded upon the chest, delivery is an easy matter, but unless the uterus has been kept well contracted down upon the child's head, one or both arms are apt to be extended upward to the sides of the child's head. In such cases the difficulties in liberating the arms are often very great, owing to the increased amount of space afforded by the curvature of the sacrum an attempt should first be made to release the posterior arm. This is best accomplished by drawing the body of the child upward and to the side, causing the posterior shoulder to sink deeper into the pelvis and furnishing more room for the introduction of the hand. Then two fingers should be passed along the side of the child to the elbow-joint, which should be pushed across the face, and brought down over the thorax. Pressure should always be made at the elbow-joint and not upon the humerus, otherwise a fracture of the humerus is liable to occur, in releasing the anterior arm, as there is rarely space enough between the symphysis and the shoulder to allow the fingers to reach the elbow. It is customary, after releasing the posterior arm, to rotate the trunk, so as to bring the anterior arm backward into the cavity of the sacrum. This is accomplished by drawing the liberated arm upward under the symphysis pubis. If the back is turned to the left, the arm should be drawn upward along the left labia, and if turned to the right it should be turned along the right labia. In making artificial rotation, it is well to bear in mind the warning of Dr. Barnes, that the atlas forms with the axis a rotatory joint, so constructed that if the head be rotated beyond a quarter of a circle, the articulating surfaces will part, and the spinal cord is compressed or torn. Therefore, in making rotation be sure that the head is rotating with the body. It is well to mention here that the body is always to be kept wrapped in warm napkins until complete expulsion of the child.

*Extraction of the Head.*—In the extraction of the head we have to distinguish, first, cases where the head has entered the pelvis and has only to overcome the resistance of the perineum; second, cases where the head is retained at the pelvic brim by contracted pelvis, stricture of the os uteri, extension of the chin, or insufficient expulsive action of the uterus and abdominal muscles.

*Extraction of the Head After it has Entered the Pelvis.*—In Smellie's method the child is wrapped in warm napkins and placed astride the operators arm, the index and middle fingers are passed into the vagina and placed in the canine fossæ, to the sides of the child's nose. By this means flexion of the head is induced. At the same time upward pressure is made with the fingers of the other hand upon the occiput; then, by raising the trunk, the face is rolled out over the perineum. In case this method fails, we should use the combined method by placing two fingers in the child's mouth and, by traction upon the lower jaw, flexion should be accomplished. With the other hand, traction should be made upon the shoulders, and as the head descends the body should be raised, whereby the face sweeps over the perineum. By the combined method, there is obtained the greatest amount of traction force, in combination with the least degree of violence to the child. As the power is exerted chiefly upon the shoulders, the fingers in the mouth are not likely to fracture the jaw. When the occiput is turned into the hollow of the sacrum, forehead against the symphysis, the process just described should be reversed, as the fingers are forked over the shoulders, the back of the child should rest upon the arm, and, with one or two fingers of the other hand the chin should be flexed, traction made downward and the forehead rotated under the symphysis.

*Extraction with the Head at the Brim.*—Schroeder, and a considerable portion of the modern German School, employ combined traction upon the shoulders and chin for all emergencies alike, whether the head be high or, after its entrance into the pelvis, as the life of the child depends upon the speedy extraction of the head, it is well to become familiar with the different procedures, so that if you fail in one you can resort to the other.

The Prague method consists in seizing the feet, with one hand, and drawing the body of the child nearly directly downward. The fingers of the other hand are hooked over the shoulders of the child, traction is exerted with both hands simultaneously and, in the absence of pain, pressure should be made upon the head by an assistant. After passing the superior strait, the procedure should be as described above.

Forceps to the after-coming head has been condemned by some, and warmly approved by others. Personally I have never had any experience with them in any of these troubles, but it is recommended by some authors in overcoming the resistance of a rigid perineum in strongly built primiparæ, but it is chiefly indicated when both chin and occiput are arrested at the superior strait. With the chin anterior the forceps should be applied under the back of the child, and the handles raised so as to bring the occiput into the hollow of the sacrum. With the chin to the rear, the forceps should be applied under the abdomen of the child, and the face of the child drawn into the hollow of the sacrum.

When the arrest of the head is due to stricture of the os uteri, the forceps will sometimes bring the head rapidly through the cervix, when traction on the feet only serves to drag the uterus to the vulva. In stricture of the cervix great care must be exercised to avoid laceration, as under no circumstances are extensive ruptures of the

lower uterine segment more apt to occur than in the forcible extraction of the after-coming head. The axis traction forceps are particularly serviceable in these cases.

## AMBER YELLOW GLASS IN THE EXAMINATION AND TREATMENT OF EYES.*

BY H. H. SEABROOK, M.D.,
OF NEW YORK;
SURGEON, NEW YORK EYE AND EAR INFIRMARY, ETC.

In these days of revolutionary scientific discoveries, among the most interesting of revelations are those bearing upon the physics of light. The exact nature of the X-ray has not yet been determined, and the discovery of radium and its properties has brought into question the law of the correlation of forces, and threatens the overthrow of the theory of the luminiferous ether. Medical workers have not considered it necessary to wait for a determination of these theoretic considerations, before applying any known forces to practical use; the X-rays are being used for valuable diagnostic and therapeutic achievements, and Finsen, utilizing well-known laws of light and color, controls the suppuration of smallpox, and institutes the most successful treatment of lupus as yet known.

While the study of phototherapy is being thus energetically carried on about us an occasional discussion as to the amount of white light proper for inflammatory and postoperative eye cases seems to satisfy the minds of most ophthalmologists. The largest eye hospital in this country is rendered gloomy and unhealthy with window shades of a dark indigo blue. Blue glasses, relics of a scheme conceived in previousness some twenty-five years ago, are still used to protect eyes, although the color is the worst, or one of the worst, for this purpose. "London smoke" is no doubt superior to blue for such protection, which is, nevertheless, only partial, and obtained at the expense of diminished vision. It has been shown that the blue-violet or actinic rays are the only ones capable of causing irritation or chemical inflammation of the eyes, having an analogous action to that upon the skin, or the photographic film. Some observers inform us that these rays do not penetrate glass, but we must evidently modify this if we accept the former statement. Photographs are taken through a white glass lens, and may not be developed in light shining through white glass; a pin hole photograph may be taken through a small aperture in amber yellow, but not in white glass. The irritating effect of light upon certain eyes is often only slightly diminished by white glasses correcting the refraction, although there is some protection from heat, and irradiation of light within the eyeball is decreased. Furthermore the spectrum with the violet rays is obtained with a prism of white glass.

In attempting what might be called photochromotherapy of the eye we must deal with peculiar conditions, in that we are working upon a complicated organ of special sense, highly sensitive to pain and irritation with a constant demand that the visual function shall not be impaired. If the suppuration of smallpox may be prevented by red light, it is natural to suppose that this color would benefit abscess of the cornea; yet red is an irritating color to the central nervous system of some persons, and its action upon the retina may be by no means pleasant. If actinic rays from electric light may cure lupus, perhaps mycotic keratitis would yield to them; yet their application to the eye might result in chemical inflammation, so that the first trial of this treatment would seem to call for caution, even in an old case of dense pannus.

The preceding considerations in the course of time directed the interest of the writer to the green and yellow rays for purposes of ocular therapeutics. The former color best protects the eyes from heat, but imperfectly from the blue rays, and diminishes the light; the latter, as obtained through amber-yellow glass, gives but little protection from the heat rays but almost perfect protection from the chemical rays.* In addition, vision is not impaired by the yellow glass, and since the yellow ray is taken as the standard for determining the index of refraction, formulæ for correcting glasses are interchangeable between yellow and white. The chromatic aberration of the eye is corrected in the only manner yet suggested, simply and practically, centrally and peripherally, by the amber yellow glasses, and dazzling reflections from such surfaces as that of the cornea, or from glazed paper and other objects, are softened and modified.

For the purpose of applying these principles to oblique and indirect examinations, I had made about two months ago, a lens with a focal distance of 2½ inches. Because of the difficulty of obtaining glass of the required color, a bi-convex lens of white glass was split and cemented upon a plain glass of medium light amber yellow. This proved to be a success, and the manufacturer has pointed out that a lens of this power, ground of colored glass throughout would be darker at the center than at the periphery, while the one described is of a homogeneous tint. With this lens there is less congestion, lacrymation, photophobia and pain in examined eyes than without it; it is, therefore, suitable for examination by the oblique method of lesions of the cornea, iris and ciliary body. Discoloration of the iris with the yellow light might cause some mental confusion to the examiner before he becomes accustomed to it, and the dulled corneal reflex makes the appreciation of a foreign body upon the cornea less easy to the novice, because of diminished contrast between the foreign substance and its background. In examination of the ocular fundus by

* Read before the Section on Ophthalmology of the New York Academy of Medicine, April 20, 1903.

* Spectroscopic analysis does not show this to be as perfect a ray filter as, for instance, glass stained with a saturated alcoholic solution of tropæolin 000, with which it was compared. Amber-yellow seemed, however, to be the most practicable color in grinding the glasses and as the sequel will show, was eminently successful for the purposes required.

the indirect method the yellow lens is more comfortable than white for both examining and examined eyes, and the picture of the background is not much changed by the lessened reflex from the retinal vessels. The sphincter of the iris is not contracted so much by yellow as white light, sustaining the suspicion already entertained by some of us that the actinic rays are the most active in causing contraction of the iris: of course the relaxed pupil has its advantages in diagnosis and treatment. Should one wish yellow light for direct examination, an adjustable glass of the desired color for the source of illumination might be used, or a reversible ophthalmoscopic mirror could be stained upon one side. A thin yellow disc to slide on and off the mirror of the "Loring" was made at my request but has not seemed particularly useful as yet.

Before proceeding to the treatment of eye diseases with yellow glasses it seems well to note some effects upon healthy eyes. Comparisons are mostly made between eyes with or without the amber yellow glasses, not between corrections in yellow or white. The glasses are numbered in the usual manner, but the darker ones seem unnecessary, and from No. 1, the lightest, to 3 all-sufficient. In the investigations described No. 2 was used unless otherwise stated. The first observations made were upon vision: in about 60 per cent. this was unchanged, in over 35 per cent. improved, in less than 5 per cent. diminished. Diminution of vision, in no case of any considerable degree and improvement, one-fourth of the time amounting to an extra line on the test card at 20 feet, occurred in eyes having an appreciable amount of regular astigmatism. Failure in correcting the increased aberration caused by a larger pupil would account for poorer vision, success in the same direction for better sight with decreased irritation from elimination of actinic rays as an additional factor. The effect of yellow glass upon accommodation is hardly appreciable, but there is probably slight relaxation. As might be expected the effect upon spectral blue and pigment blue is different. The sky has a grayish or leaden hue, and light blue stained or painted objects have a greenish tinge; darker blue pigments show more suppression of the color and may appear gray or black. Adjustment of the new color values takes place after a few moments' wearing of the glasses. These do the most good upon certain dull days when the actinic rays are strongest, and least upon rainy days. More color saturation is perhaps needed for protection from intense electric or gas light than sunlight, but less for a kerosene burner.

The indications for the use of yellow glasses in the treatment of asthenopia and ocular neuralgias are in some cases easy to determine. Take, for instance, a young girl, with little pigment in the iris and retina, who suffered from pain about the eyes and forehead after an attack of chickenpox; sph. + 0.25 was the only glass accepted and there was orthophoria; bright light produced or increased the symptoms. The correction of the refraction with white glass failed to give relief, which was accomplished by a change to yellow glass. The method would seem likely to be an important addition to the present forms of treatment for asthenopic cases with hyperesthesia of the retina, but perhaps it would be well to be cautious in its use because of possible secondary effects. Patients vary in their statements regarding the effect of blue light after the removal of their glasses and the matter is too intricate to be decided upon the theory of complementary colors. Just what place yellow glass corrections should take in astigmatic and muscular asthenopia is a matter of supposition on my part, as Messrs. Gall & Lembke, the opticians, notwithstanding their interest and energy in the matter, have been unable to grind cylinders and prisms in this glass until very recently; and I have not been able to obtain reports of results in the cases where they have been ordered. For the sake of the appearance No. 1 glasses have been used, although less effective as a ray filter than No. 2.

In cases of corneal disease, two with superficial central keratitis had improved vision with the yellow glass, and in one, the improvement seemed to be continued after removal of the glass, thus: $^{20}/_{70}$ with smoke glasses No. 2, $^{20}/_{50}$ after these were removed, $^{20}/_{30}$ with the amber yellow glass, $^{20}/_{40}$ after removal. More peripheral corneal affections, three ulcers, four phlyctenular, three with pannus were not improved as regards vision, but the latter at least appeared to have less irritation: in one of these, with chronic conjunctivitis following trachoma, the glasses were ordered, and persistent pain increasing in severity as the day advanced, was relieved from the first day they were worn; within five days ocular congestion disappeared.

In the first four cases with incipient cataract vision was not improved as shown by the test types; in two where the glasses were worn the result as regards the irritating effect of light upon the eyes was satisfactory, as it was in fact in all other cases. Just two days ago, four eyes (two patients) with incipient cataract showed improved vision in three, one from $^{20}/_{160}$ to $^{20}/_{50}$, congestion of the eyes in the latter case being relieved in a few minutes, but reappearing when the glasses were removed. This patient, forty years of age, is the third of her family under my care with premature cataract, and from the histological analogy between the crystalline lens and the skin, and the destructive action of actinic rays upon the tissue of the latter, it seemed no idle fancy to suppose that chemical action of light might have caused the lenticular disease, or to imagine a possible beneficial effect upon it in its incipiency from persistent yellow glass treatment.

The first pair of amber yellow glasses ordered by me were used successfully in a case of postoperative iritis, and it should need no argument to convince others of the utility and superiority of this color over others in such cases.

The effect of the glasses upon choroidal and retinal cases remains to be noted. A patient with

posterior synechiæ and hazy media in both eyes showed diminished vision in one eye with yellow glass before atropine, but improvement in the other, and improvement in both after atropine. Irritation was less, and it is to be understood that this is the result in all cases, whether so stated or not, either in simple tests of the eyes, or when the glasses were regularly worn. Two patients with chorio-retinitis and vitreous opacities, one severe, one mild showed improved vision.

The most beneficial results might, perhaps, be expected in that class of cases having diminished vision and hyperesthesia of the retina, as occurs with glaucoma or tobacco amblyopia, and I am able, fortunately, to report three such cases. The first had acute glaucoma of over two months' duration, in the right eye, when I saw her, out in the country, nearly four months ago. Posterior sclerotomy, followed by eserine, relieved the pain and lowered tension, but there is still ciliary injection and lacrymation; the other eye is healthy. This patient reports the relief from bad effects of light to be much greater with yellow than "smoke" glasses; better vision in the sound eye of course; the other has $V=\frac{1}{\infty}$. The second patient has chronic glaucoma in each eye with complications from excessive use of tobacco; the vision and field have improved with pilocarpine locally and strychnine internally and this improvement has been held about eighteen months. During this time the only unpleasant symptoms have been sensitiveness to light and subjective color sensations, these have been relieved with amber yellow glasses after "smoke" glasses had not met with success. The third patient, over seventy years of age, had acute glaucoma in one eye, chronic in the other, both eyes having corneal macule, which latter had previously been the cause of poor vision, worse in the eye with the acute attack, which now has $V=\frac{1}{\infty}$. The other eye had $^{20}/_{100}$, corrected, with the nasal portion of the field down to $7^{\circ}$ from the fixation point. Radical operation being considered inadvisable, posterior sclerotomy was done upon the eye with the acute attack, and eserine used in both. This treatment relieved the one eye of its acute symptoms, and the other has had no deterioration of vision or field for a year. Retinal irritation from light was annoying, and only partly relieved by "smoke" glasses, which gave $V=^{20}/_{200}$. The eyes are comfortable with amber yellow glasses and $V=^{20}/_{70}$ with them.

It will be seen that the above reports show conclusively that amber yellow glass has certain good effects upon the internal structure of the eye. Only a hint is given as to the effect upon external inflammations, for, with glasses mixed light must be admitted from the sides. In order to properly show the effect of light of any color upon external inflammation of any character, a specially lighted room would be necessary. There is a class of cases in which I am particularly anxious to see the effect of selected light, and where a failure with amber yellow glasses will not necessarily preclude success with some other color. These are the eyes with summer conjunctivitis, often with papillæ, follicular granulations, or phlyctenules, where there is photophobia with lacrymation. The irritation seems to be kept up by various forms of dust, or by bright light, but it is by no means sure that the heat rays are not a contributing cause. Treatment of these cases during the summer season has so far met with indifferent success. Amber yellow glasses are well worth trying for these eyes, since in others, they are a protection from irritation and improve vision.

118 East Seventy-second Street.

## THE TREATMENT OF CHRONIC CATARRHAL DEAFNESS (OTITIS MEDIA CATARRHALIS CHRONICA).

BY GEORGE W. HOPKINS, M.D.,
OF CLEVELAND, OHIO.

A BRIEF résumé of the etiology and pathology of Otitis Media Catarrhalis Chronica may be of profit as a preliminary to the discussion of this disease from a therapeutic standpoint.

Among the more common exciting causes of catarrhal deafness, adenoid vegetations and other nasopharyngeal abnormalities occupy a prominent place. By their pressure they excite catarrhal conditions which frequently terminate in a partial or complete occlusion of the Eustachian tube, hindering drainage and forming a nidus for an army of bacteria which subsequently invade the mucous membrane of the tympanum; the mucosa of the middle ear becomes thickened and the tympanum filled with exudate. The whole structure gradually becomes involved, the membrana tympani becoming thickened and frequently filled with chalk deposits.

Occlusion of the tube occurs with contraction of the tensor tympani, and anchylosis of the various joints of the ossicles is a later development followed by dragging in of the entire membrana tympani toward, or even against, the promontory. Even hyperostosis of the ossicles may occur.

Ultimately sclerosis, with fibrous and osseous anchylosis of the plate of the stapes, pressure upon the endolymph and interference with the circulation within the entire capsule results. Although there is an anastomosis between the vessels of the tympanum and labyrinth, it is so circuitous that pathological conditions in the latter must rather be ascribed to pressure than to circulatory disturbances.

Tinnitus may depend upon defective circulation, arteriosclerosis, anomalies of tension in the membrana tympani, tubal contraction or constitutional causes.

Hyperplastic cases are characterized by increased density in the fibrous portion of the tympanic mucosa, diminished size of the glands, reduced secretion with new tissue formation and contraction of the ligaments, resulting in dislocation of the ossicles and membrana tympani.

Finally, there is anchylosis of the ossicular chain or chalky deposits in the oval window. Some cases are due to defective teeth, as dental irritation from cavities or defective fillings may cause irritation of the otic ganglion.

Heredity is an important factor in many cases. There may exist an inherited predisposition to catarrhal or purulent inflammation of mucous membranes in general, and of those lining the cavities of the middle ear, nose and pharynx in particular.

Anatomical development is an important factor in the predisposition to ear affection. Deep niches in which are set the round and oval windows, unusual development of the promontory, extra thickness of the tegmen tympani and general reduction in the size of the attic necessarily favor adhesions and deafness after inflammation. De Schweinitz reports that an examination of 400 boys, generally healthful and athletic, in a Philadelphia school, showed hardly 24 normal drumheads.

Improper dressing (excessive dressing, perhaps, oftener than insufficient dressing); exposure when overheated and the wearing of thin-soled shoes are prolific sources of trouble.

Fully 60 per cent. of all cases are due to nasopharyngeal catarrh. Measles, pertussus, hayfever and similar affections have their influence on account of the extension of catarrhal inflammation to the middle ear. Rickets frequently figures prominently in the etiology of these cases.

Disordered digestion aggravates and perpetuates a large proportion of cases, not a few of which are unsuccessfully treated because this important causative factor is overlooked.

Gout is another important factor sometimes overlooked, gouty deposits being more frequently found in the ear than in any other organ.

Pathological defects in the ciliated epithelium lining of the Eustachian tube permit invasion of bacteria from the nasopharynx.

Five per cent. of all scarlet fever cases develop otitis media, while the rapidity with which destruction of the ear may result from diphtheria is almost incomprehensible. The ears are frequently involved in measles, but the disease rarely goes beyond an acute catarrh.

Typhoid fever may be accompanied by an otitis which is frequently overlooked.

The prognosis in cases of chronic catarrhal otitis media is not nearly as unfavorable as many suppose. The failures so common in our treatment of these cases are usually due, either (1) to insufficient study of the etiology and pathology of the case under treatment, or (2) to lack of persistency in pursuit of the treatment indicated. For the former the physician may be responsible, for the latter the patient is usually to blame, though patients are not usually so hard to manage if every promise to them is made conditional upon faithful, long-continued application to treatment. Many a case which looks hopeless can be wonderfully benefited by a year or two of persistent, rational treatment, to which the patient gives proper aid. A close study of every possible etiological factor in every case under treatment is absolutely imperative to secure good results.

Frequently the mode of life on the part of the patient must be wholly changed. General medication and close attention to general hygiene are imperative, since the effects of overtire and nervous overstrain, increased still further by the fatigue incident to a considerable degree of deafness, interfere with the nutrition of the more delicate structures of the body, and so favor trophic changes which are evidenced in the ear by still further impairment of hearing.

The diet must be closely studied and absolutely controlled in each case.

The abuse of alcohol, tobacco or other narcotics must be avoided.

The daily cold bath, unless distinctly contra-indicated should be insisted upon. Even the question of suitable underwear should be closely and strictly controlled. Some cases have been helped more by the prescription of linen-mesh underwear than by months and years of local treatment. Many patients are almost "clothed to death"; the more wool they wear the more frequently they "take cold," and the more rapidly they go on from bad to worse.

Adenoids or hypertrophied tonsils, when present, must be removed with as little delay as possible, unless some distinct contraindication to prompt operation exists. When thickening of the Eustachian mucous membrane, together with abnormally increased prominence of its folds and increased secretion from its glands cause occlusion of the lumen, means must be provided to secure ventilation of the middle ear. Appropriate treatment of the tube will usually give the desired ventilation by removing the occlusion.

Among the most satisfactory agencies for accomplishing this end, except in very serious cases of occlusion, we find medicated vapor.

By its employment vapors of menthol, eucalyptol, camphor, benzoin, iodine and other suitable remedies may be applied to the entire diseased area. Such a vapor given warm and under a proper pressure, restores the intratympanic air pressure, and mechanically stimulates the mucous membrane of the tube and tympanum. It causes an increased flow of blood to the parts, favoring absorption of recent inflammatory deposits or relieving chronic congestion due to lack of tone. It is possible also by employing an intermitting flow of vapor to massage the tympanum and ossicles with any desired force and frequency while medicating the entire mucous membrane with the selected medicament. For years the writer has found exceptional satisfaction in a special nebulizer for this purpose which furnishes a warm vapor instead of the cold vapor usually employed in this work. The instrument is made from noncorrosive metal without rubber lining or rubber parts, it being unsafe to use superheated air or warm vapor through an instrument having rubber parts. This special nebulizer also has an ozone attachment so that ozone alone or in com-

bination with other vapors may be applied to the tube and tympanic cavity, ozone having very marked stimulating qualities, which give it marked value in a certain large class of cases.

Compressed air, heated and charged with ozone constitutes one of the best agencies known to therapeutics for inflation of the Eustachian tube and middle ear, but is of little value, as is any vapor or gas for inflation, if marked occlusion of the Eustachian tube exists. This device generates ozone from an incandescent lighting current and supplies it in abundance whenever desired. In cases having a tendency to slight Eustachian occlusion, it is well to employ a spray or vapor of adrenalin to the Eustachian orifices for a moment before attempting through inflation. Indirect inflation without a catheter has some advantages in cases where it is sufficient. Unquestionably the Eustachian catheter method is very much abused, and in some hands works injury to the ear.

If the tubal obstruction be of long standing it may be necessary to resort to mechanical dilation, many employing Eustachian bougies having their tips covered with cotton for this purpose. A far better method, in skilled hands, consists of electrolysis. Dench's gold electrode, properly applied, rapidly removes tubal obstruction of long standing, but its skilful employment requires a thorough knowledge of electrotherapeutic principles. Indeed, a very excellent aurist may make a miserable failure of the operation if his training in electrotherapeutics be deficient, while on the other hand a very ordinary aurist who is skillful in the use of electricity will secure results which cannot be obtained in any other known way. To such a one the operation is reasonably simple, safe and certain. Several precautions must be observed in its employment, *i.e.*, (*a*) Neither heavy nor uncertain currents should ever be employed; (*b*) perfect current control (preferably by a shunt circuit rheostat) is absolutely imperative; (*c*) the current employed should not be of less electromotive force than 30 or more than 35 volts; (*d*) The current strength should never exceed 1½ milliamperes at the beginning or five milliamperes at the end of a treatment, and the latter amperage should be very slowly approached. Many cases require no more than four milliamperes. (*e*) Treatment should never be given less than three days apart; (*f*) force should never be employed; (*g*) reliance should be placed upon a number of light treatments rather than upon a few heavy ones; (*h*) polarity of current should never be in doubt.

These points, carefully observed, remove every element of danger from the operation and leave the opponents of the operation without any ground upon which to base their opposition. Skilled operators have obtained brilliant results in a large number of these cases, and such operators will continue to get such results regardless of any criticism which may come from those who are less skilled in applying this particular form of treatment.

If the treatment be employed with reasonable skill and with due observance of the precautions mentioned the several cases of failure will be eliminated. There cannot be much pain if the voltage and current strength are properly controlled and all necessary changes of current-strength slowly and carefully made. There can be no re-formation of stricture as a result of treatment unless the current be excessive, of wrong polarity or applied too frequently. There can be no formation of a fistula unless the operator forgets the anatomy of the parts and only then, ordinarily, by the employment of excessive current or undue force. Properly employed, this treatment causes the stricture to fairly melt away beneath the slowly advancing electrode until the tip of the electrode is felt slipping into the space beyond the stricture. This method is probably the best one ever devised for such cases of catarrhal deafness as are entirely due to occlusion of the Eustachian tube.

A nice modification of this treatment consists of using a cataphoric electrode at the anode or indifferent pole, saturating it with a suitable iodine or ichthyol solution (iodine vasogen or ichthyol vasogen being sometimes preferred), and holding it against the membrani tympani during each electrolytic operation.

During the past few months experiments have been conducted by the writer with a kind of "electric douche" which has been applied to the entire intratympanic cavity, and while it is rather early to report results, yet there is already much evidence to indicate that possibly, when fairly perfect appliances have been secured and a better technic acquired, catalectrolysis may be made to act as favorably upon old organized inflammatory deposits in the ear as it does upon similar deposits elsewhere, softening them and stimulating their absorption, in which event it will perhaps equal in importance the superheated air method, though it will doubtless require some years of work and experience to bring it to the same degree of perfection.

The promptness with which relief follows this electrolytic-cataphoric application is sometimes remarkable.

Iodine cataphoresis is a valuable adjuvant in certain selected cases, the auditory canal being filled with iodine solution and a cataphoric electrode applied, anode direct, to the tympanum.

Pneumo-massage of the tympanum externally has yielded splendid results in the hands of Pynchon and a few other experts who have paid proper attention to technic. In the hands of some others it has probably done as much harm as good. The rule governing its application is that for simple middle ear cases, slow vibrations should be practised, while more rapid vibrations are advantageous in the cases accompanied by labyrinthine or nerve involvement.

In the experience of the writer, massage with medicated vapor through the Eustachian tube has yielded more uniformly satisfactory results, but the best results cannot be hoped for unless the

vapor is as warm as can be comfortably borne by the patient.

Removal of the membrani tympani and ossicles has been practised in desperate cases by some excellent operators, but the results are of so doubtful a character that the operation should only be employed when grave melancholia from tinnitus or some similarly urgent indication exists. Some six years ago the writer was so impressed with the brilliant results yielded by superheated air in the treatment of certain articular and chronic inflammatory diseases, pathologically similar, in many respects to cases of a certain type of chronic catarrhal otitis media, that he resolved to try this agency experimentally in suitable cases of chronic catarrhal deafness. The very satisfactory results of the experiment have been reported from time to time (*Medical Record*, June 1, 1901; *Annals of Otology, Rhinology and Laryngology*, February, 1902). Scores of cases which have obstinately resisted every other form of treatment have slowly, but gradually progressed under the application of superheated air to the tympanum until marked improvement in hearing and relief of tinnitus has resulted. It is doubtful whether one in the whole number treated now by this method has perfect hearing, but every patient discharged (since contra-indications have been determined and closely observed) has been perfectly satisfied with the result.

In the early experiments the heat was secured from a crude room heater with a funnel top and a canvas sleeve air conductor, but this was soon displaced by a compressed air heater which drives the superheated air against the tympanum with as much or as little force as may be desired. A temperature varying from 250 degrees to 400 degrees F. is thus applied and is easily borne if the maximum temperature is slowly approached. Of course, *moist* heat could never be applied at such high temperatures or to as much advantage. It is unfortunately true that some of the compressed air heaters now on the market are mere toys and fail utterly to yield a curative temperature, or yielding it furnish it at an improper rate of elevation so that a curative temperature cannot be tolerated by the patient. The writer employs an electric compressed air heater which acquires its maximum temperature from a given air pressure in ten minutes and finds the rate of elevation just about right. If the temperature is then well borne it is raised still higher at the ear tip by gradually increasing the air pressure. Ordinarily the treatment lasts about 15 minutes or until the limit of toleration is reached. No fixed temperature can be employed in all cases, the operator being governed entirely by the individual toleration of the patient under treatment, the toleration not only varying widely in different patients, but in opposite ears of the same patients even under precisely similar conditions.

It is necessary, of course, that the ear under treatment shall be clean and packed with dry gauze (two thicknesses) to prevent scalding from the boiling of any moisture present, and when it is done there is absolutely no danger of burning.

It is only by taking this precaution that high temperature can be employed without burning. The benefit derived from applications of dry heat is directly proportional to the degree of heat applied and high temperatures can neither be tolerated or safely applied in the presence of any accumulated moisture. It has been pretty well demonstrated that intense dry heat stimulates the circulation through the blood supply on the posterior side of the manubrium, causing absorption of the articular deposits; removing atrophy and relieving rigidity of the tensor tympani. The ossicles lie so near the surface that they receive the full benefit of heat applied to the tympanum and adhesion between portions of the ossicular chain and the adjoining bony walls of the middle ear are readily removed.

Naturally, much better results are secured in the same period of time in hypertrophic cases than in those characterized by hyperplasia; but many cases of the latter type, which would ordinarily have been regarded as hopeless, have gradually acquired marked improvement under this treatment. Occasionally slight vertigo or headache results from treatment, but is very transient in character and requires no treatment. Vertigo may become serious if heat be applied to both ears on the same day and it is, therefore, unwise to make such applications. The writer regards as contra-indications to this treatment, arteriosclerosis, serous effusions into the tympanum and perforations of the tympanum. As an exclusive treatment it is rarely of much value in serious cases. When carefully employed it is absolutely safe unless contra-indicated. It is of little value in old subjects who have extensive labyrinthine involvement. Superheated air (especially when compressed) acts more favorably upon the ossicular chain than upon many other articulations because of the exceptional proximity of the entire bony structure to the surface.

Treatments are best given three times a week for from three to twelve months. The writer sometimes gives daily treatments for the first month, but if any additional dulness of hearing is observed as a result of treatment the intervals are immediately lengthened. A good routine practice consists of inflating the Eustachian tube and middle ear with a *warm* vapor from a good nebulizer at the conclusion of every superheated-air treatment. The superheated compressed-air treatment, when indicated and judiciously employed, *in conjunction with such other measures as may be indicated*, will give results which would be utterly unattainable without its aid.

Obstinate cases of this disease usually call for a combination of agencies, each of which has its own indications, but good judgment is often necessary to avoid meddlesome therapeutics.

Every case must be treated as a whole; every indication must be met. All abnormal conditions of the nasopharynx must be properly treated. The Eustachian tube and middle ear must be care-

fully attended to. Antiseptic washes must be used often enough to maintain a clean mucous membrane; different cases frequently requiring very different washes.

The selected irrigant in any case should be capable of dissolving the secretion to be removed, readily soluble in water, non-irritating to mucous membranes and sensitive surfaces and possess the power of penetrating surface tissues. It is an advantage if it is chemically compatible with suitable antiseptics. The sulphates of sodium, potassium, magnesium and ammonium fulfil these requirements well in cases characterized by viscid or inspissated, "crusty" secretion, provided the solutions are not stronger than two per cent. Considerable quantities of the selected irrigant should be used each time, from six to eight ounces being usually required to thoroughly cleanse the nasopharynx.

Antiseptic solutions can sometimes be employed to better advantage after thorough cleansing has been accomplished. The temperature of an irrigating solution is of some importance and should be about equal to body temperature.

In office practice some good device like the Terry electric solution-heater affords an easy and quick method of bringing the selected solution to the desired temperature for application. Cold vapors should never be employed in catarrhal cases and especially after applying high temperatures to the tympanum. Warm vapors are absolutely safe, if not too hot, and are of far greater value in treating these cases.

Of course, very high temperatures cannot be used on mucous membranes, owing to the fact that they cannot be kept dry during treatment and a temperature of 300° to 400° F. would cause scalding, hence this can be in no sense a substitute for the superheated air applied directly to the tympanum through the auditory canal, but warm medicated vapor for Eustachian and intratympanic inflation has a large field of its own, which no other agency can fill.

## THE CLINICAL VALUE OF BLOOD PRESSURE.

BY H. RICHARDSON, M.D.,
OF BALTIMORE, MD.;
LATE PATHOLOGIST TO MOUNT HOPE RETREAT; DEMONSTRATOR OF PHYSIOLOGICAL CHEMISTRY AT THE MARYLAND UNIVERSITY.

The observation of the pulse by the finger touch has been for centuries a valuable aid to the practitioner, but the knowledge acquired has never been scientifically accurate. The terms hard, soft, high and low tension, high and low pressure, are not definite, and do not admit of exact records for comparison. Like the other senses, touch has its limitations, and the terms used are relative though of clinical value. Dr. Oliver, of London, has repeatedly proved, by the conjoint use of the hemodynamometer and the arteriometer, that the finger touch is very frequently at fault in estimating the arterial blood pressure; and that the cause of this tactile illusion is a reduction in the caliber of the radial artery; the finger failing to realize a rise in the arterial blood pressure when the artery is contracted below normal size; he states that the unaided finger can only estimate the blood pressure in a general way when the caliber of the artery remains normal or is enlarged. He has found radial arteries of little more than half their normal caliber, having a mean pressure of 160 to 200 mm. Hg., which were passed by well-trained fingers as not presenting an exceptionally high blood-pressure.

Many instruments have been devised for the observation of the pulse and of the blood-pressure, but the usefulness of most of them has been confined to the physiological laboratory. The sphygmograph has largely passed into disuse for clinical purposes on account of the difficulty of its application. The weak point appears to be that the transmitter is solid, and also it is almost impossible to fix the pressure of the pad on the artery so that the pressure exerted by the pad is equal to the pressure in the artery. An instrument so arranged to insure the tracing being taken at the proper pressure, would give more certain and more valuable results. Several instruments have been devised for the purpose of obtaining accurate observations of blood-pressure for clinical purposes. Roy's oil sphygmometer was probably the first instrument which promised success; it was followed by those of von Basch, Riva-Rocci, Gärtner and others; but they only measured the systolic or maximum pressure, the arterial pressure or mean pressure not being obtainable. Dr. Oliver invented an instrument by which not only was the maximum and mean arterial pressure obtainable, but also the venous pressure. The manipulation of this instrument requires considerable skill and practice, so much so that the personal equation is a disturbing factor in comparing results obtained by different observers. Drs. Hill and Bernard have introduced an instrument which is exact and practically eliminates the personal equation in the observations.

The instrument consists of a rubber bag connected with a dial graduated in mm. Hg. The bag is securely and tightly fastened around the arm or leg of the patient, and air pumped into the bag till the pressure is sufficient to close the artery; the point of closure being indicated by the cessation of the oscillations of the needle of the aneroid. To obtain the mean pressure, the air is allowed to escape from the bag until the maximum oscillation of the needle occurs, at which point the pressure in the artery and in the bag are the same. It requires very little practice to become familiar with the instrument.

There are two pressures in the arterial system which can be estimated by this instrument, viz., the maximum or force of the systole, and the mean or the pressure in the artery. As the arteries collapse if empty, it is evident that the force required to obliterate them when full will represent the force of the blood driven into them by the heart. There would appear to be some variation caused by the pressure required to overcome the resistance of the tissues surround-

ing the artery, but in practice, if the arm is extended and the bag and collar put on as tight as possible, and the arm flexed, there is very little, if any, falsification of the results from this general cause.

Experiments on animals have proven that the pressure in the left ventricle and that registered by the instrument are the same.

If the artery were a blind tube with no outlets the pressure in it would be equal to the heart force, and the heart would be arrested; but there is during the whole cardiac cycle a continuous outflow of blood through the arterioles which causes the pressure in the artery to be about 25 per cent. less than the systolic pressure. As the aortic valve closes immediately after systole, the diastole of the heart can have no effect upon the pressure in the artery, provided the aortic valve is intact. The difference between the maximum pressure and the mean pressure is, therefore, due to the blood flowing out through the arterioles.

It has been shown that the capillary pressure is only one-fourth of the arterial pressure, consequently we would expect to find that the difference between the maximum pressure and mean pressure would be 25 per cent.

I made a number of observations on healthy individuals, taking the maximum and mean blood pressure in the recumbent position at 11.30 A.M., and found a mean pressure varying from 100 to 120 mm. Hg., and a maximum pressure from 140 to 160 mm. Hg., taking the average $\frac{\text{mean pressure } 109}{\text{maximum pressure } 150} = 0.73$, or in other words, the mean pressure is 73 per cent. of the maximum pressure; the capillary pressure will therefore be 27 per cent.

That the point of greatest oscillation represents the pressure in the artery has been proven by experiments on animals; with a manometer inserted in the carotid and the instrument on a limb, it was found that the point of greatest oscillation corresponded with the pressure recorded by the manometer.

The oscillations of the needle should theoretically represent the fall of pressure in the artery during closure of the aortic valve; I have found this loss of pressure to be equal to about 4 mm.; I have nearly always found aortic regurgitation or dilatation of the left heart if the fall in pressure was over 6 mm. Hg.

By this instrument the maximum or systolic pressure, the mean or arterial pressure, the loss of pressure in the artery during the cardiac cycle representing the flow of blood into the capillaries and by difference the capillary pressure can be observed.

It must be noted that the above observations were made with the patient in the recumbent position with the arm at the level of the heart; the patient was kept in this position for some time before the observations were taken, in order to do away with any increase of pressure from physical or mental activity. The average pulse rate at the time the observations were made was 63 per minute.

The clonic contractions of the heart, and the tonic contractions of the arterioles are the determinates of the arterial pressure; if the arterioles dilate, a larger amount of blood flows from the artery and the mean pressure falls; if the arterioles contract, less blood flows from the artery and the mean pressure in the artery rises. There is a compensatory action between the arterioles and the heart; when the former contract there is a back pressure on the ventricle, while at the same time more blood is forced through the coronary arteries, and the force of the heart systole is increased. Should the contraction of the arterioles become considerable, the back pressure on the heart may be so great as to prevent the left ventricle from emptying itself, which will produce dilatation. If the arterioles are dilated the pressure in the artery is reduced, as in exercise the heart, relieved of the back pressure, empties itself more easily and beats quicker; more blood passes to the venous side of the circulation, the arterioles regulating the supply of the blood to the venous system, and there is a greater bulk of blood passing through the body.

Under normal conditions there is a postural variation in blood-pressure. On taking the erect position the mean blood pressure rises owing to a contraction of the arterioles in the body; if this compensatory contraction did not take place, on taking the erect position the blood would gravitate to the abdomen and syncope ensue. When fatigue is so great as to become a pathological condition, the postural variations of blood-pressure are reversed, viz., on taking the erect from the recumbent position the blood-pressure falls to to 20 mm. Hg. In neurasthenia and analogous conditions I have found that the reversed postural variations of blood pressure exist, so that it would seem that at least one of the pathological conditions of neurasthenia is a failure of the vasoconsrictor nerves to react. In three cases of neurasthenia I found the following conditions:

| | Horizontal | | | Sitting. | | |
|---|---|---|---|---|---|---|
| | Pulse | Mean P | Max. P. | Pulse | Mean P. | Max. P. |
| (1) | 96 | 148 | 170 | 105 | 134 | 160 |
| (2) | 78 | 150 | 180 | 84 | 142 | 174 |
| (3) | 94 | 132 | 146 | 110 | 124 | 130 |

Standing.

| | Pulse | Mean P. | Max. P. |
|---|---|---|---|
| (1) | 110 | 128 | 145 |
| (2) | 126 | 125 | 155 |
| (3)* | 128 | 114 | 124 |

Probably in no condition is the observation of the mean blood-pressure and its relation to the maximum of more service than in the early diagnosis of Bright's disease, when the headaches, fainting spells, etc., begin, and even before the apex beat has moved to the left, a very high mean blood-pressure will be found which will at once suggest Bright's disease; it is probable that the albuminuria does not occur until the high

* Case 3 had a very weak and irritable heart.

arterial pressure has reacted through the left ventricle and caused venous congestion.

The action of the bromides on the blood-pressures is interesting. I had the opportunity to take the blood-pressure of an epileptic for eleven weeks, during part of which time he took no drugs while for four weeks he took 20 grains of bromide three times a day. During the period when he was taking no drugs the blood-pressures were usually a little above normal; but about four or five hours before a spasm the blood-pressure began to rise; on one occasion he had a spasm while the instrument was on his arm when his mean pressure rose to 227 and the maximum was above 250 mm. Hg. (The instrument only registers up to 250.) Under the bromides, both his mean and maximum pressure steadily fell, and for three weeks he had no spasm; at that time his mean pressure had fallen to 93 mm. Hg., and his maximum pressure to 135 mm. Hg. at which point he had several very severe attacks, and was confined to his room. During the bromide period his pulse rate fell from 86 to 66 per minute. This would seem to show that the action of bromides was on the vasomotor nerves, or upon the heart muscle.

In melancholia simplex I found that there was great contraction, the patients having a high mean and a low maximum pressure. In six cases the factor (mean and maximum pressure) averaged 0.94 instead of the normal 0.73, showing that the capillary circulation had a low pressure.

In mania it was difficult to obtain an observation without exciting the patient; but in a few cases observed I found both the mean and the maximum pressure very high, the maximum being high in proportion to the mean; the factor, mean and maximum pressure, being about 0.64 showing that the circulation was rapid, and that a very large volume of blood was passing through the system. In mania with depression there is a high mean and high maximum pressure; but the ratio is about normal.

In locomotor ataxia and paresis the mean blood pressure is high. In three cases of locomotor ataxia I found:

| Pulse | Mean P. | Max. P. | Factor. |
|---|---|---|---|
| (1) 95 | 180 mm. Hg. | 220 mm. Hg. | 0.82 |
| (2) 86 | 172 mm. Hg. | 210 mm. Hg. | 0.81 |
| (3) 92 | 188 mm. Hg. | 220 mm. Hg. | 0.88 |

In paresis the results were about the same except in one case where the patient was melancholic when the pressures were about normal.

In arterial sclerosis, owing to the hardness of the vessel walls, the instrument gives much too high results for the maximum pressure, but the mean pressure is probably correctly registered and is, as would be expected, high.

There is a condition of nervousness which is often met with giving a history of long-continued worry, excitement, mental strain or suppression of the emotions, in which the maximum and minimum blood-pressures are very high but in proportion, the factor being about 0.73, and in which there is apparently no dilatation or hypertrophy of the left heart, but a distinct dilatation of the right heart with venous congestion, the proportion of venous blood to arterial blood being above normal with a dry, harsh skin and evident defective capillary circulation. In such cases the continuous mental strain, acting as all emotions do upon the circulation, contracting the vessels, has produced a spasmodic contraction of the arteriolar muscle. As these cases improve under treatment the pressure returns to normal.

From the clinical standpoint, the observation of the maximum and minimum blood-pressures and their relation to one another is of immense advantage, not only as an indication for treatment but also as a measurement of progress.

The treatment of the condition of the mean pressure is generally far from satisfactory, none of the vasodilators of the pharmacopœia giving satisfaction; amyl nitrite is too fugitive to be of any value except in emergencies; nitroglycerin, though more lasting in its effects, has the defect that it accelerates the heart, and further, I have never been able to reduce the pressure more than 10 mm. Hg. with doses of gr. $\frac{1}{50}$, the effect passing off in about three hours; erythrol tetranitrate is not more satisfactory except that, owing to its insolubility, its effect will last six hours. The nitrates and nitrites of the alkalis are not reliable and in no way superior to nitric acid. The ideal drug in these cases should dilate the arterioles and not increase the heart beat, or better still, slow and strengthen it.

The suprarenal extract given internally does not fulfil these conditions perfectly; it undoubtedly slows the heart and increases the force in cases where the maximum pressure is low, and it will also increase the mean pressure, but it fails to increase the capillary circulation.

The thyroid reduces the mean blood-pressure by dilating the arterioles, filling up the capillaries, changing the dry, harsh, white skin, to a moist, soft, pink, normal condition, and, if pushed, will produce severe diaphoresis which none of the vasodilators referred to above will do; but it weakens and accelerates the heart, producing a condition of mental depression if pushed, which in neurotic patients is very undesirable. By the administration of arsenous acid and strychnine in very small doses the heart weakness and depression are somewhat relieved. If administered over a long period of time in small doses the thyroid gives good results in many cases, but as an emergency drug, where the relief of the patient is urgent, it fails.

The Shott bath treatment has given the best results. After immersion in the bath, the blood-pressure falls, the capillary circulation is improved, cyanosis of the extremities disappears, the volume of respiration is increased and the heart rate is decreased. How the simple bath of sodium and calcium chloride produces these results is not very clear. The most necessary factor in getting good results from this treatment is the temperature of the bath which should never be

lower than 96° F., and never above 101° F. If the temperature exceeds these limits the peripheral vessels are contracted and the object of the bath is frustrated. The salts in the bath act in the same manner as the carbon dioxide of the later series of baths by irritating the skin and thereby stimulating the capillary circulation.

As the abdomen is the great reservoir of the blood, it has been argued that the pressure of the water, augmented by the increased specific gravity, on the abdomen, increased the bulk of blood in circulation. In the experiments on animals it was shown that if held for a certain length of time in the vertical position, the blood would gravitate to the abdomen, the animal becoming comatose; but by simply immersing it in water, still in the vertical position, it would recover owing to the pressure of the water. But if this extra pressure were the cause of the phenomena of the Shott baths, simple pressure on the abdomen without the bath ought to produce the same result, which it does not.

The arterioles are the regulators of the blood supply to the capillaries, and consequently to the venous system; when they contract, less blood passes through them and consequently the capillary circulation is decreased. The contraction of the arterioles increases the blood pressure, which causes increased action of the heart, perhaps by forcing more blood through the coronary arteries. If the ateriolar contractions continue there is a damming back of the blood acting through the left ventricle on the pulmonary circulation, thence to the right heart producing an increase of the proportion of venous to arterial blood and a stagnation which must materially reduce the bulk of circulating blood. In such a condition a vasodilator would presumably remedy the condition which arises primarily from arteriolar contraction. If, however, the contraction was in the capillaries the vasodilating drug would have little or no effect.

The very large capacity of the capillaries causes any general contraction to have far-reaching effects on the circulation; though no nerves have been demonstrated in the capillaries it is evident that they have some means of regulating the amount of blood passing through them as on observing the capillary circulation in the mesentery the capillaries will be seen to obliterate and then to refill. It seems to me that many of these nervous conditions with increased mean blood-pressure are due to an obliteration of the capillary circulation which acts upon the circulation in the same way as arteriolar contraction. That the capillary circulation is affected by the emotions is shown by the blanching in fear, fatigue, etc., while Leonard Hill has shown how sensitive the blood-pressure is to the emotions, even working out a problem in arithmetic raising the blood-pressure 10 or more mm. Hg. The proper distribution of the blood to the various organs is probably of as great importance as the quality, and any condition which disturbs the distribution will be far-reaching in its effects.

## TYING AND CARE OF THE UMBILICAL CORD.

BY ALBERT S. HARDEN, M.D.,

OF NEWARK, N. J.;

LATE ASSISTANT RESIDENT PHYSICIAN, NEW YORK LYING-IN HOSPITAL; ASSISTANT VISITING SURGEON TO THE NEWARK GERMAN HOSPITAL.

This interesting and important subject seems to have been entirely overlooked in the numerous medical papers; and to bring before the profession the necessity of the management of this much-neglected subject this paper is submitted.

The tying of the cord, judging from experience, is performed incorrectly by half of the profession, the general technic being as follows: a ligature generally of silk or catgut, which is sterilized (?) is taken, and the cord is tied with an ordinary double knot, tying same by grasping ends of said ligature and pulling in opposite directions as hard as possible, causing great tension to be brought to bear not only on the knot, but on ligature and cord itself. Very often the ligature breaks, with the result of a defect in it and we then have a laceration of the cord. We try the same method again and probably succeed. On the other hand, silk cuts tissue when great tension is employed and we therefore do further damage. It is the practice of the author, and I think in all maternity hospitals, to use tape which is about one-sixth to one-eighth of an inch wide. This is cut into strips seven to eight inches long, giving plenty of room for tying. These strips are then put into a test-tube the end being plugged with cotton and over this a piece of linen is tied. This is then subjected to dry heat for thirty minutes. We then have a sterile and serviceable ligature. The tying should be performed by placing the first knot in place over cord, then drawing snugly, put thumbs in apposition, then, using the second joints of thumbs as a fulcrum, separate tips of thumbs holding the ligature. In this way pressure is brought to bear directly on the knot itself and the chances of breaking of the tape and of lacerating the cord is minimized. The tape is firm and does not cut the cord substances. There will, therefore, be no hemorrhage, which cannot be said when silk is used. The author has seen over 500 cases in which this method was employed, and has yet to see either hemorrhage or laceration of cord; and in 35 cases in which silk was used has seen 5 cases of laceration and as many hemorrhages. After the cord is tied take warm water and a little soap and wash the abdomen around cord gently, cleaning the vernix off, then dry thoroughly. Take a piece of sterile gauze four by four inches doubled and put in center of same a slit about one-half to one inch long. Through this pull the cord by the strings of the ligature, push gauze down onto the abdomen and place the cord on the gauze with it pointing upward; now fold the piece of gauze below up over cord, the sides over this and you have the cord enveloped in gauze and perfectly dry. Now cut the strings of your tape, you have not touched cord at all and as the cord is said to be sterile you have in no way infected it.

As regards the dressings to be used, powders, etc.; judging from the author's experience nothing but plain sterile gauze is the best dressing. There is no very serious objection, however, to powders, except that they leave a residue which hardens on the cord and on and in the umbilicus, necessitating cleaning of same, generally by the mother or some kind friend of the family, no attempt of asepsis being made and force in the majority of cases being used. The danger here is twofold, viz., injury of the umbilicus and infection. Ointments are worse, they leave a filthy surface and are splendid media for germs; alcohol used by many is good for only one reason and that is its hydroscopic power, but this is more than counterbalanced by its defects, which are first vesication and secondly, irritation. Alcohol is a vesicant and a great irritant to the delicate skin of the infant, setting up in quite a few a dermatitis which will necessitate further treatment. Again, powders, ointments and alcohol will not cause the falling off of the cord any sooner than plain dry gauze and you do not run the risk of infection, as with the plain dry dressing you can leave the dressing on until the cord falls off, and one may then be sure that there is a clean surface.

On summarizing, we have lessened chances for infection, and a falling off of the cord as soon, if not sooner, than by other dressings, against an accumulation of hardened masses of powder and of salves, or a dermatitis, and a greater liability to infection. From this summary the reader is left to choose which will be of advantage not only to his patient but to himself.

---

## THE GENERAL PRACTITIONER AND HIS RELATION TO EARLY SURGICAL OPERATIONS.*

BY E. B. MONTGOMERY, M.D.,
OF QUINCY, ILL.

In these days of ever-increasing specialism, it is not to be expected that the general practitioner or internist should be perfectly informed as to the refinements and minute developments in each special branch of practice. There are many points, however, in which he comes into close touch with them all, and in which his judgment may be of the highest importance to the welfare of the patient. There are so many patients applying to the internist at first for relief, who require at an early period expert surgical intervention, that it has seemed to me that the subject of the relation of the general practitioner to early surgical operations, was well worthy of a brief consideration by this section. I will premise all I have to say by the remark that all the surgical work referred to is supposed to be in thoroughly competent hands. It is always too early for unskilled or incompetent persons to undertake work requiring the highest technical skill, knowledge or experience, and such operations in such hands serve only to bring disaster to the patient and opprobrium upon surgery. Fools should not be allowed to rush in where "angels fear to tread," whatever may be their license or motives for so doing. But all of this, while an intensely practical matter, indeed a matter having to do deeply with medical education and medical ethics, has nothing to do with the scientific aspect of the subject under consideration. It is constantly impressed upon us by every-day experience that a very large number of cases are rendered hopeless or fail to be benefited as much as might be, by failure to secure surgical intervention at an early period. Valuable time is often frittered away by futile attempts to apply internal remedies to conditions requiring early treatment by the surgeon in order to secure favorable results. Here the general practitioner is so often the arbiter of the fate of the patient, for it is to him that such patients first apply for relief and it is only through his advice and aid that surgical aid is likely to be had. A few of the instances in which it should be his duty to promote the procuring of such early aid and it will be of interest and importance to consider.

The first condition to be considered in which a surgeon should be called early is that of appendicitis, or cases in which a diagnosis of appendicitis is probable. In my mind it is beyond question that appendicitis has been proven both clinically and pathologically to be essentially a surgical disease, and that it is dealt with by surgical methods with better results, both immediate and remote, than by purely medical management. This being the case it is certainly unjust to the patient and to the surgeon to delay associating him in the treatment to a time which might not be best or most desirable for operation. An early diagnosis and early operation, I believe, is supported by the consensus of opinion of those having the widest experience in the treatment of this disease. An early diagnosis is usually not difficult. A localized peritonitis in the right iliac region in males and children is in the vast majority of cases of appendiceal origin. In women the differentiation from a cause originating in the female pelvic organs is usually not hard to make by the usual methods of examination of those parts. The futility of medical treatment in a large number of cases is shown by the disastrous termination of many of them apparently of mild type. There may be at first severe pain soon becoming bearable, a temperature not exceeding 101.5° F. and pulse 100, there may be no inflammatory mass and everything may point to an early recovery, when on the third or fourth day a perforation may occur from gangrenous appendix and the patient soon collapses from septic peritonitis. As Nothnagel has well said, unless one operates early, by principle, in every case, such results cannot be avoided occasionally. The rule laid down by Hemmeter[1] in his work on "Diseases of the Intestines," should, therefore, be followed wherever possible. He says "Let the practitioner associate an experienced surgeon with himself in every case of appendicitis, even

* Read before Illinois State Medical Society, April 29, 1903.

the simplest and mildest." In intestinal occlusion the same rule holds, so that no valuable time should be lost in attempting a cure by purely medical methods. Favorable results are much more likely to follow early, than late operations. According to statistics compiled by Naunyn of the results of 288 cases of intestinal occlusion treated by surgical intervention, when the operation took place during the first forty-eight hours the recoveries were 75 per cent. After the third day the results grew less favorable, sinking to 35 per cent.

Nothnagel, Boas and Naunyn all agree that when the character of the occlusion can be well made out, medical treatment should not be continued longer than forty-eight hours. Hemmeter thinks that "the obscure cases running an intensely acute and rapid course, should be *operated on at once*. These cases usually being so very fatal without operation that every life saved in this manner is a gain and a gift, pure and simple." Acute cholecystitis not rapidly subsiding is another condition in which surgical advice and frequently early surgical operation is indicated. Kehr,[2] whose experience in the surgery of cholelithiasis has been greater than that of any living surgeon, emphasizes the importance of operation before the pathological changes in the gall-bladder have not advanced too far, and while the gall-stones are still in the gall-bladder, not having moved into the deeper ducts. He says "*the slight dangers of early operation stand in no sort of a relation with the great dangers of the disease itself*. This conviction ought more and more to gain strength, and not only in medical circles but even in the lay public to gain a firm footing. It is very lamentable that the scientific practitioner has scarcely any opportunity of influencing the wider circles of the people, for just as soon as he opens his mouth in any sort of a society not a medical one, he is exposed—often, indeed, with reason—to the charge of advertising. The natural doctor and the empiric, however, scatter the poison of their teaching ever further, and we are obliged to connive at stupidity and folly gaining always more and more."

The cases which may be safely left to the internist are cases with acute obstruction of the common duct proceeding normally, and those with frequent colics each time attended with the passage of stones. But cases of seropurulent cholecystitis and pericholecystitis with adhesions, and cases with chronic obstruction of the common or cystic ducts, should certainly be cases for skilled surgical interference as early as possible. According to Kehr's experience, the mortality of these operations is less than 1 per cent., while not over 90 per cent. of the cases show even an apparent cure under medical treatment.

In perforation of a typhoid ulcer in the course of typhoid fever, the only hope of saving the life of the patient lies in the earliest possible operation. After the shock of the perforation is over, every hour the infection of the peritoneum becomes more intense, and as Keen says "*if the operation is not done within about twenty-four hours after its occurrence there is practically no hope of recovery.*" Early diagnosis and prompt operation is the keynote to any success here. As J. B. Murphy,[3] of Chicago, has recently said in his report of a case of typhoid perforation operated on by him last November with favorable results, "In the past the diagnosis of perforation was based on the combination of symptoms included under the term collapse, which he believed to occur a few hours after the perforation took place. At present the diagnosis of acute infectious perforative peritonitis is based upon the symptoms of pain, nausea, and vomiting, localized tenderness, circumscribed flatness on piano percussion, and hyperleucocytosis, in the order named."

An operation should not be postponed until collapse symptoms appear. In a contribution of "Surgical Features of Typhoid Fever," in the last volume of Johns Hopkins Hospital Reports,[4] the authors, McCrae and Mitchell, say that it is the practice in that hospital to have a surgeon see all cases of typhoid fever presenting any abdominal features, following a suggestion previously made by Osler that the earliest symptoms of perforative cases should be studied and watched by the surgical colleague as well as the physician. Out of seven cases so studied and operated on in the hospital within the last two years, two have recovered. In one of the cases with favorable result, the operation was made within seven hours after the first appearance of localized abdominal pain and rigidity, but before the appearance of any marked distention. In the second favorable case, the operation was made twelve hours after the first appearance of abdominal pain and rigidity, and about four hours after distention first appeared.

Cases presenting indications of extra-uterine pregnancy should have surgical advice, and often surgical operation at a very early period, and as these cases, as well as the other types previously considered, first come into the hands of the general practitioner, upon his judgment frequently depends the fate of the patient. Whenever a woman, having passed one or more menstrual periods and supposed to be pregnant, is suddenly seized with severe pain in the lower abdomen, feels faint and develops symptoms of shock, as pallor, feeble pulse, clammy sweat, cold extremities, etc., it is probable that she is suffering from hemorrhage from rupture of the extra-uterine gestation sac. It goes without saying that a competent surgeon cannot see her too soon, and neither expectancy or stimulating medication should be relied on. These are cases where early or immediate operations are frequently life saving. Early operative interference is indicated in septic infection of the uterine appendages. In an address on this subject, Henrotin[5] well contrasts the two courses which may be pursued. The method of delay, in which he says "you see your patient regularly, hypnotize her to the best of your ability, amuse her with poultices and hot

douches, give her quinine as an antipyretic if her temperature goes up, or quinine as a tonic if it goes down, and tell her to have patience, and if she does not recover, when her tubes and ovaries are ready and ripe, yourself or one of your friends will remove them." Or, as early as you find an exudative mass against the uterus, and the organ fixed, incise the posterior vaginal fornix and drain the affected seat of the trouble.

While not necessary to the saving of life, the general practitioner should advise more often and more decidedly than he does the early operation for the radical cure of hernia. When the almost entire absence of mortality of the operation in competent hands is considered, and the result in removing completely what is otherwise a most distressing disability, the only wonder is that it is not advised as a matter of routine in all patients capable of tolerating any surgical interference, between the ages of five and sixty years. This has been my invariable practice for several years, and the results have been uniformly gratifying. Three years ago the late lamented Prof. Christian Fenger performed the Bassini operation for me, for the cure of a herna acquired by me one week previous, and the result has been a permanent cure. The precentage of recurrences in operations properly done is extremely small. I know of no surgical procedure giving more satisfactory results, and its early performance should be much more common.

Accumulations of fluid in the pleural cavity should be removed promptly by aspiration under aseptic precautions, and such patients not subjected to the prolonged disability produced by waiting for results from internal medication. Delafield,[6] in a recent article on "The Treatment of Pleurisy with Effusion" details 200 cases treated in his service in Roosevelt Hospital from 1886 to 1901, all of which were aspirated. There was infection in no case and the patient usually made complete recovery within two weeks. In private practice his results have been still better, a number of them being entirely well within a week, and none of them sick longer than two weeks. With such results as these by aspiration, how unnecessary seem the long delays incident to courses of medical treatment, and reserving aspiration as a last resort for effusions which seem to menace life. The experience of Dr. E. Fletcher Ingals[7] is that where aspiration is done early in empyema, we may expect from 95 to 98 per cent. of recoveries. Early aspiration is to be advocated in effusions of any size into the pericardium. I have seen more than one patient die where this was refused, that I am confident might have been saved by its timely performance.

Carcinoma affecting certain portions of the body is only amenable to early operation following early diagnosis, this being particularly true of the mammary gland, the uterus and the rectum. The recurrences which follow later operations are disheartening to the surgeon, and only tend to lessen the confidence of the people in surgical art. In his monograph on "Diseases of the Breast" Bryant[8] says that the only hope of cure lies in early diagnosis and radical removal. "Waiting till symptoms develop" means waiting till all hope of cure is gone, he thinks, and Senn[9] in his classical work on "Tumors" says: "The writer is confident that when the public has become educated in reference to the necessity of early operations, and the profession recognizes the importance of carrying the incisions far beyond the palpable tumor and the infected glands, the percentage of permanent recoveries will be increased greatly." In this view all surgeons heartily concur, and the duty of the general practitioner is most plain. As the adviser of his clientele on matters pertaining to their health, he should make known to them the importance of seeking professional advice at once in any abnormality or induration occurring in the mammary gland in women above forty years of age. The importance of this can be still more fully realized when we consider that 85 per cent. of all growths appearing here are malignant in character. Only through this means of educating the public will these cases be brought to the attention of the surgeon when his aid will be most effective.

Rectal troubles causing obstipation should very early be subjected to a thorough rectal examination. If this were done habitually very few cases of carcinoma of the rectum would be permitted to go to the inoperable stage. As it is, most of the cases, when referred to the specialist, have passed beyond the period when surgical operation would be justifiable. Hemmeter says that 90 per cent. of the cases of malignant disease that have come under his observation, have brought the ready-made diagnosis of bleeding piles or fistula. In carcinoma of the uterus the same complaint is to be made. Hitherto, statistics relating to ultimate recovery have been most discouraging. At the Ninth German Congress of Gynecology, May 29 to 31, 1900, Prof. Freund said he was able to report only two cases of cancer of the uterus permanently cured by surgical operation in twenty-three years' experience. He learned by inquiry in the various clinics of Germany that after abdominal extirpation with removal of the larger portion of the parametrium and glands that the mortality is 24.5 per cent., and recurrences within the first year 46.6 per cent. Baldy[10] in a paper read before the Gynecological Section of the American Medical Association in June, 1901, expresses the view that the results achieved by surgery in this disease are "surgery's disgrace." He estimates that the number of permanent cures following operation is less than 5 per cent. These bad results he attributes to lack of proper attempt to discover these cases early, and a disinclination to advise immediate operation when they are discovered, under the misapprehension that a later operation saves a large percentage of cases. He says that when the family practitioner realizes that early operation gives the only hope of cure, he will watch his female clientele more closely with this end in view. Hemorrhage with possibly beginning loss of flesh and strength is, he thinks,

the diagnostic sheet anchor in the early stages. Bleeding begins very early—early enough to give warning of what is coming. A woman who has passed the menopause, and a year or two, or possibly several years later has a show of blood from the genitalia, almost invariably has uterine cancer. He would be suspicious of any hemorrhages occurring without reasonable cause. These at any time may be significant, and call for careful examination. The symptoms may be explained by polyp erosion, or a benign ulceration, but most frequently will cancer be found so early that the pathologist will be uncertain in his diagnosis. The earliest possible operation is the only way of making a better showing in our number of cures, and for this opportunity the surgeon must depend on the wisdom of the family practitioner in making an early diagnosis and advising immediate operation.

Dr. G. Frank Lydston[11] has recently called attention to the fact that the profession at large should be impressed with certain facts in regard to prostatic enlargement. He called attention to the fact that while the use of the catheter may for the time relieve the symptoms of prostatic obstruction, that the longevity of patients after the habitual use of the catheter has been once begun, is, on the average, about five years, and those five years, years of suffering. It is obvious, therefore, that, when the enlargement and obstruction have reached this degree, the case must be referred to the genito-urinary surgeon. An early operation performed before the onset of bladder and renal complications gives a favorable prognosis, and should always be advised at this time. The operation done at a later period, as I know from observation of several cases in which prostatectomy has been done as a last resort, after the obstruction had become so great that a catheter could no longer be used and the bladder and kidneys had become affected, is not satisfactory, and the results are only palliative.

A considerable number of conditions in which delayed operations are undesirable might be mentioned, but I will close with a few in which the family practitioner is the determining factor in bringing about early relief. One is the early removal of postnasal adenoid growth, in which delay is, in most instances, fraught with evil consequences, not only on the general health, mental development, and facial formation, but also from the danger of ear complications arising, and the greater seriousness of infectious diseases, such as scarlatina and diphtheria, in such subjects. Another condition in which timely interference is desirable is in acute purulent collection in the middle ear, in which an early incision of the tympanic membrane may prevent the extension of the disease to the labyrinth or meninges.

This list might be almost indefinitely extended, but enough has been said to show at how many points the general practitioner comes in contact with the surgeon and specialist, and to demonstrate the importance of his having carefully considered opinions regarding the pathology and treatment of many affections which very early demand operative care.

## OTHER CAUSES THAN SYPHILIS FOR PARESIS.*

BY H. PRESTON SIGHTS, M.D.,

OF PADUCAH, KY.

So much has been written on the subject of general paralysis of the insane, and yet we know so little of its pathology, I necessarily feel some timidity in presenting this paper, though the thoughts and experiences I relate have been worked out by mental struggles and energies extending over a period of six years, and I feel that these observations are worth repeating, at least for consideration and judgment.

One hundred years ago there was very little thought about this fatal form of mental trouble recognized as paresis; in fact, as late as thirty years ago, very little was written about it in medical literature. So it can now be considered a disease of modern civilization, especially confined to busy commercial and crowded cities. The increased percentage, as will be shown in the following statistics, and with it the recognized fatality of its termination, should attract the attention of the profession to active investigation. I was prompted to present these views from a consideration that the theory of paresis, being due to syphilis mainly, was a stumbling-block, liable to produce many blunders in the effort to discover some curative treatment of this form of mental disease, impeding and discouraging the profession in their hopeful search of a cure for paresis, and a possible preventive line of advice to susceptible cases.

My own observation has impressed me with a determination to search earnestly for the causes of this disease, and in this search I find that records from every hospital and asylum that has furnished statistics show it to be a disease of the prime of life, and is most prevalent at the age of forty-five years. All reports show the minimum susceptibility of age to be twenty-five years, increasing to the age of forty-five years and decreasing again to the age of sixty years, showing conclusively that it occurs at the period of greatest mental activity and is discouraging to the idea held by some of the profession that syphilis was the only cause for paresis, as the ages of twenty-five to thirty-five is the most common period for contracting syphilis.

* Read at the Fifty-third Annual Meeting of the American Medical Association, before the Section on Nervous Disease.

I do not doubt for a moment the statistics that there is a history of syphilis showing in a large percentage of cases of paresis, but think that it is the result of mental agony and worry that produces such mental strain as to cause the disease instead of the effect of syphilitic poison on the brain cells. As a proof of this I refer to the reports in medical literature of the countries of Japan and Egypt, where syphilis is very prevalent and paresis is scarcely known. This can be explained better by recognizing the fact that these people have very little mental worry and are low in the scale of modern civilization. The most convincing argument, however, to my mind is found in my own experience in the treatment and observation of this disease in the four years service as First Assistant at the Western Kentucky Asylum, where there was quite a large percentage of the colored race treated, and I did not find more than two per cent. of paretics, while among the whites it reached 18 per cent. Yet, we know that among the colored race syphilis is the most prevalent. This can be accounted for only by the absence of mental worry in the colored race.

These facts in addition to the rapidly increasing percentage of cases, as shown at the present, shows very conclusively that the theory of "No syphilis, no paresis" is not correct.

In referring to other causes than syphilis for paresis, I wish to be understood to mean the effect of the syphilitic poison on the brain cells or nervous system necessary to cause the organic changes produced by this disease necessary to result in paresis. I take it that the mental worry and distress of mind is independent of the disease, for you can satisfy the patient's mind of a permanent cure and assure him of no recurrence in the future, thereby saving him from being a paretic. In the same way you would stop a business man from the strain of his mental labors.

There is a recognized specific for syphilis and why should not paresis in its early stages, when due to it, yield to the constitutional treatment and result in recovery. This is not too much to expect of a specific treatment in any disease. Syphilis has existed for more than 1,000 years, and I am sure the old, acute observers would have discovered paresis had it existed to any great extent in the early ages, for the mortality in paresis is appalling in all the statistics examined by me. In Kraft-Ebing's Clinic, Dr. Asher and Dr. McDonald of Manhattan Hospital, and many others, only one case of recovery is recorded, and yet an increase of 75 per cent. in the last twenty years is shown. There must be other causes than syphilis for paresis. Out of 123 cases that have come under my care 87 had no history of syphilis, and, I am convinced, never had the disease.

The percentage of paresis as compared between male and female is ten to one and syphilis four to one. Mendel shows that in 1876 the percentage of paresis in agricultural districts of Schleswig-Holstein and others was $4^{5}/_{10}$ per cent. while in Berlin it was 26 per cent., an indication that specialties in cities and the concentration of mental energies to one single vocation or single strain of thought should be classed as prevailing causes for this disease. I believe that statistics will show that one in every ten among the insane are paretics. If this is true I feel that a close inquiry as to the causes of paresis should be inaugurated by the profession and a careful scrutiny made of the failing health of a complaining business man among our patrons. The fact that it is fatal in the average cases in so short a period, one to two years and often earlier, should make us look to the sources that produce this fatal form of disease and search out the early symptoms with the information that we can gather as to the causes rendering an earlier diagnosis possible.

General cerebral strain, irregular eating and sleeping are the prevalent causes. This includes any mental worry that is kept secreted in the mind of the individual, such as brooding over financial failures or imaginary troubles that excite the mind and produce mental agony, as in the case of a man who has contracted syphilis that has listened to a lecture from a semimedical professor on the horrors of syphilis, producing in the individual all the mental horrors that the loathsome disease is associated with, making them become extremely observant of themselves; every little pimple about their body or face they attribute to the disease and think they will have facial manifestations of the disease to stamp them as syphilitics before the world, or decide in their minds, in case they marry, their children would be deformed and miserable beings. No wonder they terminate in paresis.

If such demagoguery in medicine could be stamped out and in its place a cheerful assurance of recovery from this disease, we would have fewer paretics. The medical profession is to blame, in a large degree, for these impressions on the laity. We find among the insane syphilitic manias that are not attributable to the influence of the disease on the constitution, but to the impression on the mind of the dreaded results of the disease. These cases only differ from the paretics in the temperament of the individual. If the former, one talks to every one and listens to him, and in the latter all the worry and agony of mind he keeps to himself and broods over it.

So I am persuaded that civilization brings in its wake an increased percentage of this disease.

Sexual excess and alcohol should not be omitted as prevalent causes of this disease, for I am sure they are recognized as important factors, and in the same way exaggerate the physiological functions of the brain. The central excitement of the sexual excesses produces a hyperemia of the brain. Alcohol does the same. So does any form of mental strain, a continuation of which frequently will produce paresis. We can take a remedy that will produce a hyperemic condition of the brain and produce paresis.

I have kept syphilis continually before me in this paper, because I think it stands at the head of mental worries and anxieties. The earnestness

with which I have gone into this paper can only be excused on the grounds of my having exerted every therapeutic means I possess to restore a few patients in whom I recognized the trouble early, but without result.

I am convinced that neurotic elements are important factors in the majority of cases. Next to this element comes the extremely sensitive, whose thoughts and acts are controlled in a great degree by the manners and acts of their friends, bringing upon them mental worry over imaginary wrongs, etc.

Actors, playwrights, inventors, commercial men and bookkeepers—all such individuals as have sensitive natures should be observed closely, for they are usually the victims of this disease. As an example, one of the most popular artistes of the American stage, whose character is as pure as our ideal of modern womanhood, whose peace of mind was destroyed by a single breath of slander which sent her to an asylum. I call to mind one individual, a lawyer, who stood in the front rank of his profession, but the sensitiveness of his nature drove him from the bar, his sensitiveness increasing until his imagination kept him in an angry sea of torture, unbearable to a human being, which resulted in a complete giving way of his mental forces.

I am justified in concluding as follows:

1. That syphilis is present in a large percentage of the cases of paresis.

2. That it is certainly an important factor in disturbing the peace of mind in a susceptible and sensitive individual, whose pessimistic tendency is hereditary.

3. That in the majority of cases where syphilis is present, the mental worry and nervous strain keeps the brain in a state of hyperemia, causing loss of sleep and appetite that results in paresis, in the same way that any other mental worry will precipitate this disease in a susceptible individual.

4. The prevailing cause of paresis is an overworked mind in centralizing the mental energies without relaxation, whether worry over financial troubles, syphilis or a concentration of the mental forces in any single avenue of life.

## MEDICAL PROGRESS.

### HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

**Hemoagglutination of Human Blood.**—This phenomenon has been studied by U. Biffi (Ann. d'Igiene Sper., fasc. 11, Year 1903) with the view of determining its applicability to clinical diagnosis and medical jurisprudence. His investigations were carried out with 140 individuals; 100 of whom were apparently healthy and 40 were afflicted with various diseases, such as malaria, pneumonia, typhoid, etc. He found that the blood or serum of a malarious subject had the power to agglutinate the blood of another malarious subject and also healthy blood; this finding coinciding with that of Lo Monaco, Panichi, Grixoni and others; but the author believes the phenomenon to be of little diagnostic value in latent malaria, from the fact that it is present in many morbid conditions as well as in normal serums; a higher agglutinating power having been found by him in two normal specimens than in the serums of diseased conditions. Ascoli's statement that normal blood has the power—though feeble—to agglutinate its own cells was not confirmed in Biffi's work. On the other hand, he found that this power was present to a high degree in diseased conditions; for example, in a febrile malarial seizure, the first stage of pneumonia, etc. That the phenomenon of autoagglutination was in no way related to that of coagulation, was amply proven by the author's work. The relation between the agglutinating power of the serum and the agglutinability of the red cells was carefully studied by the writer; as a result of which investigations he lays down the general rule that in normal human blood, the agglutinating power of its serum is in inverse ratio to the agglutinability of its red cells. The greater the agglutinating power of the serum, the feebler the agglutinability of the cells. Pathological blood exhibits, as a rule, the same characteristics, but a certain number of exceptions to the rule were seen by the author in diseased conditions; and he found that the agglutinating power of the blood-serum in a given individual might be quite different from that of exudates and transudates occurring in the same individual. Biffi believes that the differences in agglutinating power of the serum in different individuals, as well as the difference in agglutinability of their red cells may be utilized in medical jurisprudence. For example, in a case in which it might be necessary to decide from which one of several individuals a blood spot is derived. This he believes may be determined in the following manner: By means of the usual technic applied to legal medicine, the red cells should be extracted from half of the blood spot and suspended in a small quantity of 0.85 per cent. NaCl. A drop of the blood-serum from the suspected individual should then be mixed with this emulsion of red cells. If the former show high agglutinating power toward the latter, the blood spot is not derived from that individual; for it has been shown that the serum of normal blood will not agglutinate its own cells. If the extraction of the cells from the spot is not possible or if they are too deformed for use, the serum may be extracted from the other half of the spot, and this used to test its agglutinating power toward the red cells of the suspected individuals. These same tests may be applied when it is desired to learn whether a number of blood spots are derived from the same individual. In the author's belief, a small specimen of blood from the body of any individual who has met death by violence, should invariably be preserved for use in such legal examinations. Much of the value of the medico-legal application of agglutination phenomena depends upon their constancy. This the author has investigated and has found that in a period of from three to four months there is but very little variation in these phenomena in a given individual and this variation is only such as might be attributed to faulty technic. He also found that blood spots retain their agglutinability and agglutinating power for a prolonged time.

**Sputum as a Culture Medium for Tubercle Bacilli.**—Following up the work of other experimenters along this line, G. Guyot (Gaz. Osped., July 5, 1903), has made a series of experiments to determine the value of the sputum as a culture medium for the tubercle bacillus. He describes the technic as follows: The required amount of fresh sputum, free from extraneous matter, is collected and allowed to digest upon the water bath from eight to ten hours; after which it is filtered while hot and sterilized for three-quarters of an hour, when it is again filtered. The filtrate can now be used for cultural purposes, in the liquid state or incor-

porated with agar to render it solid. The proportion of agar should not be more than one per cent. With the liquid sputum, the author obtained excellent homogeneous cultures which could be used after ten to twelve days and these he considers not inferior for use to those prepared after the methods of Arloing and Courment. In the combined sputum and agar, the development of tubercle bacilli is promptly evident. Within twenty-four hours proliferation of the bacilli may be recognized in cover-glass preparations made after the method of Hesse; and rapid growth of colonies may be seen with the naked eye upon the third day. The colonies are white and opalescent, their appearance differing in this respect from ordinary glycerinated agar cultures. The author holds that the simplicity and economy of the preparation of this culture medium should favor its general adoption in laboratory work, and further, that these studies serve to emphasize the necessity of disinfectant and astringent treatment in catarrhal affections of the respiratory passages.

**Effect of the Nucleoproteids of Heterogeneous Blood on the Red and White Cells.**—Certain dangerous signs having been observed from the transfusion of blood, various hypotheses have been advanced concerning the mechanism of the pathogenic influence upon the organism, exerted by the blood of an animal of different species. The effect of the nucleoproteid of parenchymatous tissues upon the morphology of the blood and upon the mechanism of coagulation has been noted by many observers. G. GUERRINI (Gaz. Osped., July 5, 1903) has sought to determine the effect of the nucleo-proteids of the blood of healthy animals upon the number and proportion of red and white cells in the blood of an animal of different species. For this purpose, rabbits were injected with the nucleoproteids of dogs, chickens and eels; the nucleoproteids being extracted by Woodridge's method. The author found that injections of a one-per-cent. aqueous solution of sodium carbonate had no apparent effect upon the number of red cells, but a slight increase in the leucocytes followed such injections. Injections of a one-per-cent. solution of nucleoproteids heated to 60° for thirty minutes had practically the same effect as injections with plain sodium carbonate. Injections of the nucleoproteids of rabbits slightly increased the white cells, though they failed to affect the red. Injections of a one-per-cent. solution of the nucleoproteids of heterogeneous blood (dogs, chickens and eels) in one-per-cent. sodium carbonate diminished the absolute and relative number of red cells and increased the white both absolutely and relatively.

**Symbiosis of the Influenza Bacillus.**—The possibility that symbiosis with certain invisible bacilli may be an important factor in prolonging the life of the bacillus of influenza, is the statement made by M. NEISER (Dert. med. Woch., No. 26, 1903). He bases this on the fact that he has been able to cultivate influenza bacilli through some twenty generations, which were derived from a case of measles conjunctivitis and were associated with xerosis bacilli. In every case the influenza bacillus died out unless this symbiosis with the xerosis bacillus was kept up. It is suggested that the latter may have modified the agar-agar, which was the medium used, in such a way that it was rendered more favorable for the growth of the influenza bacillus. The author also found that the diphtheria also served as a "nurse" for the bacillus of influenza, but not so successfully as the xerosis bacillus.

**Sedative Treatment of Hyperchlorhydria.**—In the examination of the gastric secretion of patients exhibiting the symptoms of hyperchlorhydria, G. CAMPO (Rev. de Esp. Méd., June 20, 1903) has not infrequently found the acidity to be normal; and in many patients in whom symptoms of this condition subsided after treatment, he has found the acidity as high as before treatment was instituted. Hence he believes that the discomfort experienced by this class of patients is largely due to hyperesthesia of the gastric mucosa toward hydrochloric acid. He therefore treats his patients suffering from so-called hyperchlorhydria with sedatives, and has obtained the best results from menthol 0.50, cocaine hydrochlorate 0.50 and alcohol 10 c.c. Each drop of this preparation represents 1½ milligrams of menthol and cocaine respectively. The patient experiences great relief from five or ten drops of this solution given at the onset of distress, and the relief is of longer duration than that obtained from alkalies. The dose is gradually diminished after a few days and dropped altogether after subsidence of symptoms. A permanent cure is sometimes effected with this treatment, but the symptoms may return after a time as they do when other remedies have been used.

**Anastomotic Circulation of the Heart.**—An interesting condition of the heart was discovered at an autopsy by G GALLI (Münch. med. Woch., July 7, 1903). Though the right coronary artery was entirely obliterated, the parts of the heart supplied by it were normal, while with patent left coronary a sclerotic patch was found in the walls of the left ventricle. By careful dissection of the vessels, an anastomotic branch was discovered which ran from the intact left coronary to the right below the point of occlusion, thus permitting of a circulation in parts of the artery which otherwise would have atrophied. This case illustrates well that the heart, like other organs, possesses a power of adaptation to pathological changes whereby its function for a long time at least, is not interfered with, provided only these changes are not sudden in their development.

**Pseudo-tuberculous Bacilli.**—That the means of distinguishing the true from the pseudo-bacillus of tuberculosis are not always reliable, is shown by the following case, reported by R. MILCHNER (Berl. klin. Woch., July 20, 1903). In a patient, who had suffered from numerous hemoptyses, a physical examination showed the presence of a localized area of pulmonary dulness, bronchial breathing and small vesicular râles. Examination of the expectorations showed acid-resisting bacteria, closely resembling the true tubercle bacilli and leading to the diagnosis of a pulmonary tuberculosis. Against this supposition appeared the good general condition of the patient and the rather unusual site of the area of dulness over the lower lobes. Inoculation experiments on animals proved negative. Later on the expectorations assumed a very fetid character and the patient finally died from exhaustion no doubt induced by the loss of blood from the numerous hemorrhages. Autopsy showed an extensive bronchiectasis and a large bronchiectactic cavity, but no signs either macroscopic or microscopic, of any tuberculous process. The sections had been hardened in either formalin or alcohol, and no traces of any varieties of bacilli were found, although they were readily demonstrated in large numbers in the sputum before the death of the patient. The author accounts for the discrepancy by assuming that the staining properties of the pseudo-tubercle bacilli were entirely lost by the preliminary treatment of the sections with alcohol and formalin. He suggests that in doubtful cases, frozen sections should be examined and in order to avoid alcohol in dehydrating, the tissues should be imbedded in levulose.

**Detection of Blood in Feces.**—Stimulated by the recent theory that chlorosis is really brought about by constant slight hemorrhage into the gastro-intestinal tract, O. ROSSEL (Deutsch. Arch. f. klin. Med., Vol. 76, No. 6), suggests the following modification of an old

blood test for examination of feces: About 30 grams of feces are dried, powdered and freed of fat in the Soxhlet apparatus. The powder is then treated with glacial acetic acid, and shaken out with ether. By means of the usual guaiac or aloin test, hematin could then be readily detected in this ether. Care must be taken to use only fresh guaiac. A positive test was still obtained after the ingestion of only three cubic centimeters of blood. No food or drugs behave similarly except large doses of chloride of iron. The feces of a large number of chlorotic girls examined did not contain any more hematin than is normal, but as an aid in the diagnosis of ulcer or cancer of the stomach the test is invaluable.

## PHYSIOLOGY.

**The Enzymotic Decomposition of the Nucleic Acids.**—There are series of physiological and pathological conditions, according to T. Araki (Hoppe-Seyler's Zeitschrift, Vol. 28, Nos. 1 and 2), that lead to a dissolution of the substance of the cell-nucleus. This phenomenon is found in its widest application in the absorption of animal tissues; moreover, cells rich in nucleins and cell-products, such as the male sexual elements, can undergo normal dissolution, as has been demonstrated in the testicles of the brook-trout. The disappearance of the nucleus is not necessarily associated with the destruction of the entire cell, but may take place within the unchanged cytoplasm, as is familiarly seen during and after conjugation of the paramecia. The suggestion is strong that some enzyme affects the nuclear substance in the same way that pepsin acts upon albumin. The author found that the nuclear substance obtained from the red blood cells of birds, is rapidly dissolved by trypsin and that an extract of the thymus also contains an enzyme capable of slowly digesting the cell-nucleus. The thymus gland contains two forms of nucleic acids, namely, nucleic-acids *a* and *b*. The author discovered that trypsin is capable of splitting acid *a* with the formation as intermediate products of acid *b* and nucleothymin acid, which are further decomposed on prolonged digestion by means of trypsin. The extract of the thymus contains an enzyme which is capable of bringing about these identical changes. Erepsin, the peptone-splitting ferment of the intestinal mucosa, is also capable of splitting the nucleic acids. Moreover, in the auto-digestion of the intestinal mucosa, the constituent nucleic acid *a* is transformed into the more soluble acid *b*. Long-continued digestion of the mucous membrane results in a considerable reduction of the content of nucleic acids. Similar nuclein-splitting ferments were found in the liver and spleen. It is of peculiar interest that the nuclein group exhibits the same characteristics as the albumin and carbohydrate groups, namely, it exists in the tissues in an insoluble or colloid form, which under the influence of enzymes is transferred into a soluble form cast evidently also into smaller atomic groups.

**Transplantation of Submaxillary Gland.**—The investigation of the technic and physiology of organ-transplantation will probably bring to light many facts of practical value in medicine and surgery. D. Ottolenghi (Arch. Ital. de Biol., June 10, 1903), in transplanting pieces of submaxillary gland about the size of a pea, from one rabbit into the kidney or spleen of another, found that a large part of the transplantation suffered rapid death, only the peripheral portion remaining alive. In the former, with the exception of certain small portions, there is an early necrosis of the epithelium of the salivary ducts, the necrosed material falling into the lumen of the ducts, while the basket-cells remain alive, become infiltrated with fat and later undergo active karyokinetic multiplication, forming within the membrana propria at first one and later several groups of seemingly epithelial elements arranged in concentric circles; these finally block up more or less completely the cavities of the ducts. It is probable that in the formation of these cellular groups these participate to a slight degree with the epithelial elements of the intercalary canals, at the points where they are in connection with the salivary ducts. The cells of the acini can undergo multiplication when the glandular elements of the latter have suffered necrosis. In the peripheral portion of the transplantation, within the acini as well as the intercalary canals, there is a marked multiplication of glandular elements, which does not seem to lead to a new formation of acini nor of secondary canals, but which serves perhaps simply to replace certain destroyed elements, and to increase the size of the acinus the length of the intercalary canal. This proliferation ceases toward the eighth day, at which time certain retrograde changes take place even in the salivary ducts, which are transformed anew into canalieuli lined with a single layer of cells. The author has not been able to discover in the transplanted portions any new formation of solid epithelial growths such as these described by Lubarsch.

**The Physiological Action of Certain Phenanthrene Derivatives.**—It is generally known that morphine is derived from phenanthrene, a cyclic hydrocarbon having the symbol $C_{14}H_{10}$; the basic character of morphine being determined, like that of all other alkaloids by the presence of nitrogen. According to P. Bergell and R. Pschorr (Hoppe-Seyler's Zeitschrift, Vol. 38, Nos. 1 and 2) all the investigations that have so far sought to attribute the physiological action of morphine to single atomic groups, have been carried out almost entirely upon nitrogenous compounds related to morphine. The authors sought to determine to what extent the physiological action of morphine depends upon non-nitrogenous constituents, more particularly phenanthrene and its non-nitrogenous derivatives. They find that phenanthrene itself is quite inert, but that oxyphenanthrene or phenanthrol ($C_{14}H_9OH$) produces in mammals severe tetanic seizures. The position of the hydroxyl group in the molecule has no influence on the physiological effect. Similar symptom-complexes are produced by a carbon- and a sulpho-acid of phenanthrene. No narcotic effect was observed in this entire group. To what extent the effect of phenanthrol may be brought into relation to that of morphine which contains the phenanthrol-complex, and whether the behavior of this class of bodies affords any explanation of the tetanic components of morphine-action,—both of these questions the authors consider as still unanswerable. Substantially different from the action of phenanthrol and its carbon-acids, is that of derivatives of phenanthrene-equinone. These substances both in the test-tube and in the organism, show a decided power of forming methemoglobin, which power is to be attributed to the prepondering influence of the quinone-group. None of these compounds produces the above described tetanic state. Episin, a methyl derivative of phenanthrene, also produces methemoglobinemia. It is significant that in pigeons which show an extraordinary resistance toward morphine, severe toxic manifestations are produced by episin. Evidently there is some connection between the narcotic and other manifestations of morphine and the methemoglobinemia produced by some of its derivatives.

**Certain Constituents of Yeast.**—The internal administration of this substance in furunculosis and allied conditions, lends some interest to the research undertaken by O. Hinsberg and E. Roos (Hoppe-Seyler's Zeitschrift, Vol. 38, Nos. 1 and 2) on the constituents of ordinary beer-yeast. They find that this contains two

different forms of cholesterin, three different fatty acids, a colorless ethereal oil having the odor of hyacinths, phosphates, peptones, gluten-casein, purin bases, considerable quantities of albumin and cellulose-like compounds. As to the medicinal value of yeast, they find that living as well as dead yeast has a mild laxative effect, which is to be attributed to the fatty substance present. This fat was also found effective in certain cutaneous affections.

**The Effect of Alcohol upon the Excretion of Uric Acid.**—In a series of metabolism experiments, and hourly period experiments in which the urine was collected each hour during the day, S. P. Beebe (Proc. of the Amer. Physiol. Soc., Amer. Jour. of Physiol., July 1, 1903) found that the use of 75 to 80 c.c. of absolute alcohol contained in diluted alcohol, whisky, beer and port wine, produced in all but one individual a marked increase in the uric acid excretion. The increase began in most cases in the second hour after the meal and reached the highest point at the fifth hour. In the experiment where 50 c.c. of absolute alcohol, suitably diluted with water, were taken without any food after the usual period of fasting, a very marked diuresis was produced, but a decrease in uric acid was noted. This indicated that the effect produced is due to a disturbance in the metabolism of the purin bases of the food.

**Experimental Contribution to the Physiology of Fasting.**—The effect of prolonged fasting in dogs upon the functional activity of various parts of the gastro-enteric canal, and upon the anatomical elements of the thyroid gland, was studied by A. G. Barbèra (Archives Italiennes de Biologie, June 10, 1903) with the following results: The secreting fibers of the submaxillary gland contained in the tympanic nerve preserve their electrical excitability to the very last moments of the life of the fasting animal. An electrical stimulus of the tympanic nerve causes a marked, although less than normal, increase in the secretion of saliva. In this instance there are even periods of latent and survival excitation. The stimulation of the cervical sympathetic, on the other hand, produces frequently no secretion of saliva. The subcutaneous injection of pilocarpine augments the secretion of saliva, which is completely arrested by a subcutaneous injection of atropine. Curare injected into the veins increases the secretion. After the injection of pilocarpine, the stimulation of the tympanic nerve still further increases the salivary flow, while it cannot arouse this after it has been inhibited by the action of atropine. With the nerves remaining intact, a small piece of paper moistened with acetic acid and placed on the buccal mucous membrane, excites an abundant secretion of limpid, watery saliva. This secretion obtained in all the experiments above described, when chemically investigated, showed the absence of sulphocyanide of potassium, and by means of the test of artificial digestion, failed to reveal the presence of any diastatic ferment. This is not surprising inasmuch as it is well known that under normal conditions of feeding, the saliva of dogs, according to most investigators, contains no alkaline sulphocyanides, and, according to all workers, contains no ptyaline. The author found the same tenacity of function under conditions of fasting in the gastric secretory fibers of the vagus nerve, and the glandular cells of the mucous membrane of the stomach, although the gastric juice was reduced in quantity. It also contained very little free hydrochloric acid and pepsin. Intravenous injection of curare excited a secretion of gastric juice having the same character as that produced by stimulation of the vagus. The same relations were found with respect to the fibers of the vagus that preside over the pancreas, to the intrapancreatic nervous ganglia and to the secretory cells of the pancreas; the pancreatic juice obtained by the various means, retaining, although in a restricted degree, the power of transforming albumin into peptone, and starch into sugar. Upon histological examination, the author together with D. Bicci, found that in the case of the suprarenal glands there is a reduction in size of the cell-bodies and nuclei, the diminution of the protoplasm being greater than that of the nucleus. This phenomenon is more pronounced in the cortex than in the medulla. The same reduction in size of the protoplasm and nucleus were found in the thyroid gland. The latter, at no period in the fast, ceased to elaborate the colloid substance in which are supposed to be the active principles of the gland. There is also a diminution of intercellular substance. The nuclei diminish in size relatively less than do those of the suprarenal gland.

**The Fermentative Processes of the Liver.**—A research was undertaken by V. Ducceschi and M. Almagia (Archiv. Ital. de Biol., July 10, 1903), with the object of determining to what extent the presence and activity of the soluble ferment contained in a tissue, are immediately dependent upon the histological integrity of the cellular elements of the tissue; also whether the study of the enzymic activities of a tissue profoundly changed in its structural elements, would allow any differentiation between that part of the functional manifestations connected with the properties and integrity of the protoplasm as a cytological structure, and that part which depends, on the contrary, upon the presence of soluble enzymes in the cellular juices. Further, they hoped to determine in the special case of the liver, upon which the investigations were carrried out, whether the action of phosphorus, pushed to the point of causing the severest forms of degeneration, would modify the activity of the oxidizing ferment of this organ, and whether the absence of the oxidative processes, to which certain authors attribute the genesis of fatty metamorphosis of the tissues, can be explained, at least for the liver, upon the basis of an alterative of the activities of the oxidases contained in it. They obtained the following results: In a liver in which, as the result of phosphorus poisoning, considerable fatty metamorphosis has taken place, the activity of the oxidases is not diminished, at least in the beginning, in comparison with the normal liver. It can not, therefore, be admitted that the diminution of the oxidative phenomena of the organism, regarded by some authors as consecutive to phosphorus poisoning, can be attributed to a direct action of the poison upon the oxidizing ferments. There is no appreciable difference between the content of lipase in a fatty liver and that of a normal liver. The study of the functional capacities of an organ markedly changed in the intimate structure of its cellular elements, in the cases detailed above, serves to distinguish the enzymic activities from those bound up in the integrity of the structural elements. This is possible in taking account of the fact that the enzymes have no tendency, at least in the instance studied, of leaving cells which are the seat of intense necrobiotic processes. The proteolytic enzymes of the liver exert no apparent action upon the activity of the oxidases. In the case of old animals compared with young ones, the quantity of oxidases in the liver is found to be markedly diminished.

**The Biochemistry of Certain Nucleo-histones and Nucleo-proteids.**—The discovery by Lilienfeld that the nucleo-histon, obtained from the watery extract of the thymus by precipitation with dilute acetic acid, is capable, in the presence of salts of calcium, of transforming fibrinogen into fibrin, was the first of a series

of valuable data concerning the catalytic powers of these nuclear bodies. A. Herlitzka and A. Borrino (Arch. Ital. de Biol., June 10, 1903) report the results of their investigations of the problem as to whether the biochemical action of the nucleo-proteids is a general one for all these substances, or whether it is specific for each nucleo-proteid, depending on the function of the organ from which it is obtained. Lilienfeld considered nucleo-histon as the zymogen which, under the influence of the salts of calcium, is split into histon and nuclein, the latter inciting the coagulation of the fibrinogen and therefore revealing itself as the fibrin-ferment. Huiscamp showed that the nucleo-histon of Lilienfeld is not a chemical entity but is a mixture of nucleo-histon and nucleo-proteid, the former existing in the nucleus, the latter in the cytoplasm of the cell. He believed that these substances are the zymogens of fibrin-ferment, which is but the combination of calcium with the zymogen. The authors find that nucleo-proteids and nucleo-histones behave like acids. The nucleo-proteids alone and not the nucleo-histones have a destructive action on hemoglobin, which action is a general one for the nucleo-proteids of several organs. The nucleo-histon as well as the nucleo-proteid of the liver destroys glycogen; this action is a specific one and is not possessed by the nucleo-proteids or nucleo-histones of the thymus and kidneys. The results so far obtained lead the authors to conclude that the biochemic action of these nucleins is specific when the corresponding metabolic function of their parent organ is specific, and this action is general when the corresponding function is common to several organs. The authors were not able to cause the transformation of carbonate of ammonium into urea by means of these substances. In studying the possible glycolytic action of these substances they attained certain interesting though unexpected results, namely, the nucleo-histones of the thymus and the kidneys have no glycolytic power; the latter is very slight in the case of the nucleo-proteid of the liver, a little stronger in that of the thymus, stronger still in that of the kidney and maximum in the nucleo-histon of the liver. Bearing in mind the different distribution of these two bodies with regard to nucleus and cytoplasm, we may conclude that the nucleus of the hepatic cells is endowed with a strong glycolytic power, while their cytoplasm has this only to a slight degree or none at all. The reverse is the case with the thymus and kidneys. In this connection is pointed out the difference between what the authors denominate extrinsic and intrinsic metabolism. The latter has to do with those anabolic and catabolic processes in which there is the construction and destruction of the living proteid substance. On the other hand, extrinsic metabolism comes into play when the cells exert a chemical action on the substances that come into contact with them, but which do not form part of the living protoplasm. This is the form of metabolism which the authors are investigating. For example, the action of the liver on glycogen and on glucose. With regard to this organ it thus appears that the nucleus as well as the cytoplasm can share not only in the intrinsic metabolism of the cell, which has been known for a long time, but also in the extrinsic metabolism; at any rate, they share in these different processes to a different degree. While the nucleus as well as the cytoplasm of the liver cell destroy glycogen, only the nucleus destroys glucose and only the cytoplasm destroys hemoglobin. This destructive action in hemoglobin is, however, exercised also, although to a slighter degree, by the cytoplasm of the cells of the kidneys and thymus, while the nucleus never participates in this action. One may conclude that all the cells of the organism share more or less in the destruction of hemoglobin. It thus appears that the catalytic phenomena of the body are not always to be attributed to enzymes produced by the living cell, but that they are also peculiar to certain chemical substances produced by the living cell, and forming part of the protoplasm. The catalytic action of the nucleo-proteids is exercised not only when they are in solution but also when they are in suspension. Neither alcohol, corrosive sublimate nor chloroform inhibits the destructive effect of the nucleo-proteids of the liver on hemoglobin. This whole series of experiments suggests lines of inquiry of extreme interest to physiology and practical medicine.

**Influence of Speed, Temperature and Practice on Metabolism.**—Every research that throws light on the mysterious metabolic processes of the body is welcomed by physiologist and clinician alike. To the large number of painstaking investigations of all the factors that in any way influence the exchange of material in the body are now added those of N. Zuntz (Pflüger's Arch., Vol. 95, Nos. 3-4). He finds that contrary to the case in man and the horse, speed in dogs has no perceptible effect on metabolism for a unit of distance. With increased body-temperature, the metabolism for the resting body, and in the case of the respiratory work is increased. The muscles, however, perform a certain amount of work with the same expenditure of material as in the case of normal temperature. The amount of expenditure of tissue for single acts of the musculature is considerably reduced by practice. But in the case of any definite piece of work, practice does not cause any saving of metabolism in the case of any other, not specially practiced, operation. The greater the exercise of the muscles, the greater is the metabolism of rest, just as in the case of forced proteid feeding.

**Size of Body and Metabolism.**—As the result of a series of experiments on dogs, B. Slowtzoff (Pflüger's Arch., Vol. 95, Nos. 3-4) found that during horizontal movement of an animal, the smaller the animal the greater the amount of work for the same mass moved a given distance. During rest, metabolism is dependent on the extent of surface of the animal, although this is not the only factor that determines the degree of metabolism. The expenditure of work during horizontal motion is only approximately proportional to the extent of bodily surface; there are others, as yet unknown, factors that cause individual deviations from this rule. The expenditure of work during climbing is markedly different for different animals, no regular relationship between these differences and size of body having yet been discovered.

**Anatomy of Portal Anastamosis.**—Since the surgical treatment for cirrhosis of the liver has resulted so favorably in many instances, the normal anastomotic channels between the portal and systemic circulations have become the subject of considerable investigation, in order to understand more fully nature's methods of relieving the distressing symptoms of this disease. R. Floyd (Med. Rec., July 4, 1903) has found by dissections that these are from normal sites of anastomosis between the portal and systemic veins in the adult: (1) Anastomoses at the lower end of the esophagus which lie chiefly between the mucous and muscular layers of its walls; (2) rectal anastomoses between the inferior hemorrhoidal veins flowing into the internal pudic, the middle hemorrhoidal flowing into the internal iliac and the superior hemorrhoidal branches of the inferior mesenteric; (3) the accessory portal veins of Sappey. These are veins in the suspensory ligament of the liver which establish anastomoses between the liver and the veins of the diaphragm and anterior abdominal wall; (4) the retroperitoneal veins, which join the veins of

the posterior abdominal wall to the duodenum, pancreas and part of the colon where these lie in direct contact with posterior wall of the abdomen.

**Effect of Suprarenal Capsule on Blood Vessels.**—An investigation of the precise action of adrenalin on the blood vessels of a rabbit's ear under varying circumstances was made by S. J. Meltzer and C. Meltzer (Am. Jour of Physiol., July 1, 1903) with the following results: The subcutaneous injection of suprarenal capsule exerts a distinct effect on the blood-vessels of the ear. In normal animals a large, distinctly poisonous dose causes blanching of the ear. On the other hand, a medium dose causes a moderate but distinct dilatation of the blood-vessels. In rabbits in which the vasomotor nerves were cut on one side, a subcutaneous injection of a medium dose of adrenalin induced a distinct contraction of the vessels on the operated side and a dilatation on the unoperated side. Apparently adrenalin is but very little oxidized in the subcutaneous tissues.

**The Significance of Diabetes.**—It would be interesting, if space permitted, to review the entire subject of the physiology of glycogen in all its relations, as presented in a treatise of 398 pages by E. F. W. Pflüger (Pflüger's Archiv, Vol. 96, Nos. 1 to 8). It will suffice to review his conclusions as to the real nature of the physiological changes that lie at the basis of diabetes mellitus, which conclusions are of extreme practical interest. To Claude Bernard must be given the credit for the discovery not only of glycogen, but also of the fact that the nervous system exercises a powerful influence in the conversion of glycogen into sugar. Furthermore, he located in the floor of the fourth ventricle the so-called "diabetes center," for the puncture of this region increased the amount of the sugar in the body to such an extent as to occasion its appearance in the urine. This increased saccharine output was attributed by Claude Bernard to nerve impulses transmitted along the vagus nerves to the liver, but the later researches of C. Eckhard have shown that these impulses pass along the splanchnics instead, so that sections of the latter prevents the increased output of sugar. A fact of great importance was pointed out by the famous French physiologist, namely, that artificial diabetes is the result of a stimulation and not of a paralysis of function. It had been shown that certain salts as well as other substances produce glycosuria by stimulation of the sugar center in the medulla oblongata. Bernard thought that the influence of curare, morphine and puncture of the medulla, in producing diabetes, acted through the nervous system on the blood-vessels, leading to an increased circulation and therefore to an accelerated activity of the glycolytic ferment of the liver. The late experiments of Heidenhain have shown that after poisoning with atropine stimulation of the cervical sympathetic produces a secretion from the submaxillary gland, although the circulation in the latter is markedly reduced. This made it clearer that specific secretory nerves control the activity of the various glands. Analogy would indicate that in the splanchnic nerves there are not only fibers innervating the hepatic blood-vessels, but also fibers whose specific energy consists in exciting the sugar formation of the liver. This last is brought about immediately by means of a diastatic ferment. It would appear that the nerves, acting upon the cellular substance cause a splitting off of this ferment, which is a decomposition product of the protoplasm. According to Pflüger, this fact explains the phenomenon that in the course of a series of convulsions preceding the death of an animal, there is an associated innervation of the liver, expressing itself in the formation of a large quantity of ferment and the consequent rapid accumulation of sugar. From this explanation it can be rapidly understood how other provinces of the nervous system than those already mentioned can come into relation with the formation of sugar. Stimulation of the central stump of the depressor nerve, or of the cervical sympathetic, section of the right or left sciatic nerves and certain diseases of nerve-trunks, such as neuralgia of the trigeminal nerve, paralysis of the facial nerve and apoplexy, have all produced glycosuria. Knowing the ease with which stimulation of many different nerves produces glycosuria, one is tempted, from the standpoint of the diabetic, to deprecate this mechanism. The physiologist, however, inquires after the possible purpose of such an arrangement in the body. The author finds this purpose in the fact that as the muscles and other tissues use up by active work their supply of reserve food, some provision must be had for notifying the liver that more nutritive material is required. In this is found the significance of the reflex nervous stimulation of the liver. In this wonderfully efficient mechanism one sees an expression of the law formulated by Pflüger, namely, the law of self-regulation. The muscular contraction that creates the need, at the same time occasions its satisfaction. As in the case of the regulation of the heart-beat there are two antagonistic systems of nerves, one increasing and the other diminishing its work, so it appears that for the regulation of the content of sugar in the blood there are provided two antagonistic mechanisms. In this way pancreas-diabetes is most naturally explained by the supposition that the rising sugar-content of the blood occasions the separation from the pancreas of a substance which, passing into the blood, diminishes the sugar-forming activity of the liver—either by acting upon the sugar center of the medulla or upon the substance of the liver cells directly. The acceptance of the hypothesis of these two antagonistic mechanisms would remove all difficulties in the way of a clear explanation of the significance of diabetes. These difficulties centered in the fact that frequently in cases of severe diabetes the pancreas is not only apparently, but also actually, entirely healthy. If, as the result of certain conditions in the sensory nerves or of the brain or spinal cord, or as the result of direct stimuli of the liver cells, the production of sugar is extraordinary, then the inhibitory activity of the anti-diastase of the pancreas is no longer sufficient to bring about the normal equilibrium. Here is to be seen diabetes in spite of a healthy pancreas. If this organ is diseased no anti-diastase is produced, and the normal reflexly aroused formation of sugar continues in the liver, with the accumulation of this substance in the blood, for the normal inhibition of the sugar-output is absent. Another difficulty was found in the fact that certain cases occur in which the entire pancreas seems to be degenerated, without the presence of diabetes. It is impossible, however, to state that there are not a few cells which, although diseased, are capable of exercising their function. It is furthermore possible that in cases of carcinoma the weakening of the vital forces causes such a marked diminution of the sugar forming capacity of the liver that even without the need of inhibition no diabetes results. All the organs of the body stand in reciprocal relationship with the liver, in order to regulate the needs of nutrition. This relationship is rendered possible above all by the nervous system, but also by means of certain substances that are produced by the various organs. A continuous play of forces and counterforces determines the dynamic equilibrium that corresponds to health. It is therefore easy to comprehend how it is possible for apparently innumerable substances to bring about glycosuria. It appears nevertheless open to consideration that an error of metabolism may give rise to a substance that produces glycosuria,

and Hans Leo seeks in such a substance the origin of diabetes. But this will not explain puncture diabetes nor pancreas diabetes. For the latter seems to be due not to the presence of any substance, but to the absence of some substance. In the blood of diabetics there is found acetone, which, according to Ruschhaupt, produces glycosuria, but which is rather the result of this disease. There is again to be taken into consideration the fact that a substance which produces glycosuria in healthy individuals may perhaps have the opposite effect in diabetics. Such a substance is morphine, which causes glycosuria in sound individuals and lessens it in those suffering from diabetes. These, at first sight, puzzling facts are easily explained, if one takes into consideration the circumstances that the regulation of the sugar-formation of the liver, like that of the heart-beat, is brought about by accelerating and inhibitory processes. In the healthy morphine stimulates both sets of processes, but those that accelerate the production of sugar are the stronger. In diabetics the accelerating processes, being continually at work, are thereby weakened, hence the morphine administered, while still arousing both sets of processes, gives to the inhibitory ones the upper hand. This is similar to the phenomenon in which, after section of the freshly exposed sciatic nerve and stimulation of the peripheral stump, the vasoconstrictor prevail over the vasodilator nerves. If stimulation be deferred until a day after section of the nerve, the vasoconstrictors losing their irritability more rapidly than the vasodilators, stimulation of the peripheral stump causes expansion of the arteries. Starting out with the supposition that the formation of sugar in the organism under normal conditions, depends upon a dynamic equilibrium of the various functions, it is easily understood how a great many substances can produce glycosuria. Every foreign substance has some untoward action in our body. However this substance act, one cannot expect that it will effect force or counterforce in an equal degree. It will disturb the equilibrium. Many clinicians oppose the doctrine that diabetes is a neurosis, inasmuch as autopsy frequently discloses no disease of the brain, spinal cord, liver or pancreas. But the crudest logic alone asserts that there can be no disease without a diseased organ. Moreover, those very diseases in which pathological anatomy frequently finds nothing, are diseases of the brain. Those clinicians who will not recognize in diabetes a neurosis report that frequently purely psychical causes lie at its base. Unanimous are all authorities in this domain, that there is but one reliable remedy for this disease, namely, opium. According to a well-known clinician, opium is valuable even though the case of diabetes is not one of nervous origin. According to Pflüger, opium is always efficient merely because every case of diabetes is founded on a nervous basis. The latter is often the necessary result of another disease, which is no neurosis, so that the diabetes is merely a symptom.

**The Effect of Laked Blood upon the Heart.**—The result of a series of experiments performed by E. Pratzenburg (Pflüger's Archiv, Vol. 95, Nos. 11 to 12) showed that the blood of the ruminants and particularly that of the rabbit, guinea-pig, horse, pig and man, after dissolution of the red blood-corpuscles, is not in a condition to nourish the isolated heart of the frog, while the same varieties of blood, in the same concentration, but with the red corpuscles intact, afford a necessary food for the heart. In complete contradiction to these results are those in which the cystolic blood of cats and dogs has kept up the activity of the heart for hours at a time. These results agree with those obtained by Langendorff, who found that the isolated heart of the cat and dog can be nourished by the laked blood of the same animal, which is not the case, however, with the rabbit. If the various forms of blood used in the above experiments be compared, there will be found marked differences in the content of a certain substance, which, provided largely in the red corpuscles, is by their dissolution set free and thereby acquires the opportunity of exerting upon the heart an influence which, in the intact condition of the corpuscles, it is not able to manifest. This substance is potassium. The forms of laked blood that showed an abundance of $K_2O$ were those which had a particularly deleterious influence upon the frog's heart. On the other hand, those forms of blood poor in $C_2O$, even in the cytolytic condition, were excellent cardiac nutrients.

**The Absorption and Fermentative Splitting of the Disaccharides in the Intestine.**—The results of a series of experiments performed on dogs by F. Rohmann and J. Nagano (Pflüger's Archiv, Vol. 95, Nos. 11 to 12) showed that of the three disaccharides, cane-sugar is absorbed the quickest, next comes maltose, and last of all milk-sugar, which is absorbed much more slowly than either of the others. The absorption of the disaccharides is better in the upper than in the lower part of the small intestine, and is slower than that of the simple sugars that are formed from them by splitting. The amount of sugar absorbed is also dependent upon the concentration of the solution of sugar present in the intestine. Moreover, the absorption of water is dependent upon the kind of sugar present in the intestine, and, in the case of any one form of sugar, upon its concentration. In seeking to bring the greater absorptive capacity of the jejunum into some numerical relationship with the latter, the authors find that the weight of the mucous membrane relatively to its length is without exception far greater in the jeunum than in the ileum. Moreover, one gram of jejunal mucous membrane takes up more sugar than one gram of mucous membrane in the ileum. The concentration of the solutions of sugar in the intestine need not be higher than 5 per cent. in order that all the sugar eaten should be absorbed. The water of cane-sugar solutions is more quickly taken up than that from solutions of maltose or milk-sugar. On the other hand, water is more readily absorbed in the ileum. The spontaneously secreted juice of the jejunum contains very little invertin, which is able to split up only a small portion of the sugar absorbed. While cane-sugar and maltose are split up to a certain degree before they are absorbed, milk-sugar is not split up. Although in the absorption of a two-per-cent. solution of cane-sugar in the ileum no invertin is secreted by the mucous membrane, yet the latter has the power of splitting up the sugar, if not completely, at least to a great degree. This power of the mucous membrane is greater in the case of the jejunum. Five per cent. is approximately the concentration of sugar, in the presence of which the inverting capacity of the jejunum as well as the ileum is capable of splitting the absorbed sugar into dextrose and levulose. If there enter the intestine solutions of sugar of a greater concentration, it is possible that cane-sugar enters the circulation unsplit. It is then cast off by the kidneys as a foreign body. The inversion that is caused by an enzyme present in the mucous membrane exceeds that which results from the action of an enzyme liberated from the mucous membrane. Moreover, the inversion of cane sugar occurs as soon as it come in contact with the intestinal mucous membrane. These results do not agree with the earlier experiences of physiologists. Enzymatic activity has been hitherto considered as possible only in solutions, in the secretions, or in the extracts of organs. According to Hoppe-Seyler, in such solutions the ferments act like dissolved electrolytes.

*e.g.*, invertin like hydrochloric acid. According to the author, this analogy would not hold at the present day, for the solutions of enzymes are not true solutions but colloidal solutions. It is possible that invertion exists in a colloidal form in the cells of the intestinal mucosa. It decomposes the cane-sugar when the solution of the latter merely comes in contact with the cells. What has been found true with regard to the inversion of cane-sugar is also true of maltose, with the exception that dextrose only is formed from maltose, and the maltose secreted by the ileum is relatively more abundant than the invertin. As regards milk sugar it was found that the mucosa in the upper part of the small intestine splits this sugar only at times and then in very small amounts, while the membrane of the lower parts of the intestine act upon it very slightly or not at all. This failure of enzymostic splitting explains the slow absorption of milk-sugar.

## OBSTETRICS AND GYNECOLOGY.

**Morphine-Scopolamin Narcosis in Gynecology.**—It is rather disappointing to perform larger gynecological operations with morphine and scopolamin injections, according to S. Flatau (Müuch. med. Woch., July 14, 1903), for the amount of ether or chloroform necessary to produce complete relaxation was almost as large as under ordinary conditions and retching and vomiting were prominent after-effects. By increasing the doses of the two drugs, however, smaller operations, such as vaginal plastics, could be done successfully even without ether or chloroform. With three doses of ⅙ grains (1.01) morphine at intervals of one to two hours and $^1/_{60}$ grains (0.0012) scopolamin, it is, however, necessary to examine the heart, lungs and urine of the patient most carefully. In 22 out of 30 cases the narcosis was perfect; the respirations were deep and regular, the face somewhat flushed and the pupil dilated. In the other, the excitation was so marked that small amounts of chloroform were necessary. Vomiting or other after-effects did not occur, in fact the patient awoke in excellent condition 4 to 8 hours after the operation. It is well to give a trial injection the night before, to be assured that no idiosyncrasy toward the drugs exists. With all care the author was so unfortunate as to lose one case, but here probably a degeneration of the heart subsequent to hemorrhage was present. For general use in surgery and in obstetrics this method of narcosis must still be regarded as too dangerous.

**Abdominal Hysterectomy by "Décollation."**—This operation, the essential feature of which lies in amputation of the neck of the uterus (décollation) prior to removal of the body, was originated by J. L. Faure (Trib. Méd., July 4, 1903) some three years ago, and has been practised by him since that time in the majority of cases requiring abdominal hysterectomy. The author makes the section at a point corresponding to the uterine isthmus; after which, the body being no longer held down by the vaginal attachment of the cervix, it is a comparatively easy matter to sever the sole remaining attachments to the pelvis, that is, the broad ligaments. In the absence of too extensive adhesions between the uterus and rectum or adnexa, the isthmus is most readily reached from the cul-de-sac of Douglas. The section is made from this point with a pair of curved blunt scissors, and the body left freely movable and easily subjected to its further detachment from the pelvis. In the presence of extensive adhesions in Douglas' cul-de-sac or of a retroflexed uterus, the isthmus should be attacked from the front; that is, within the vesico-uterine cul-de-sac, where it may be reached and resected from before backward with the curved blunt scissors. In the author's opinion, preliminary section of the neck of the uterus gives to abdominal hysterectomy a facility and simplicity which should lead to the general adoption of this method.

**Pregnancy Complicated by Fibroids.**—When one has seen patients with multiple fibroids pass through the course of pregnancy, labor and puerperium in an entirely normal way, or has discovered such growths for the first time after the uterus is emptied, Henry C. Coe (Am. Jour. of Obstet., June, 1903) thinks that one is apt to regard with disapproval the sweeping statements of those alarmists who see danger and death in every case of pregnancy complicated by fibroids. Fortunately the chances of conception, especially in the case of large tumors, are comparatively slight. Olshausen (Veit's Handbuch der Gyn., 1897, Vol. II, p. 7,651), by combining series of observations, estimates that 30 per cent. of all women with fibroids are sterile, while Winckel states that 41.6 per cent. of women with fibroid uteri who have borne children are uniparæ. No statistics have been given showing what proportion abort in the early months. Cases of pregnancy complicated by fibroids may be included under four headings, viz.: (1) Those in which pregnancy will doubtless go on to full term with prospect of a normal delivery; (2) those in which the patient must be kept under constant observation in view of the necessity of possible interference; (3) those in which there is considerable risk to the mother or child, or both, before and during labor; (4) cases in which surgical interference is absolutely indicated. Hence the treatment may be: (1) Entirely expectant; (2) non-surgical, with the possible anticipation of the date of normal labor; (3) surgical, either (a) conservative, or (b) radical. Where the pregnancy had not advanced beyond the third month one would be influenced by the previous history. The writer feels that it is the obstetrician's duty to warn a young woman against pregnancy where she has a fibroid tumor which may give rise to serious trouble, even though it has never caused any marked symptoms. If she is determined to marry, nevertheless, the propriety of performing a conservative operation (myomectomy) for the removal of the tumor, may be considered. Under proper limitations this would be quite justifiable, and numerous successful cases have been reported in which normal pregnancy and labor have followed. How far it is possible to go in advising married women with fibroids to avoid conception is a question which each one must answer to his own conscience. In the presence of a neoplasm which has already acquired surgical importance, it is certainly unwise to allow the patient to incur the additional risk of a pregnancy which can only terminate unfortunately.

**Therapeutic Feticide: it's Medicolegal Aspect.**—Of late there has been a great deal of discussion upon this subject by the various French Societies, and in an able paper Ch. Maygier (Obstetrique, May, 1903) sets forth the following conclusions on the subject: (1) The physician should incur only the responsibility in the terms of a common duty; that is to say, if it is possible to be relieved of all charge of mistake, imprudence or of negligence, by putting aside the scientific aspect of the question of advisability of such procedure; (2) the surgeon should not perform feticide without the formal desire of the patient, who should be possessed of all her mental faculties and in full realization of what is being done; (3) the operation should only be done in cases of exceptional urgence or in other conditions which cannot be prevented, under which circumstances the physician may intervene without the knowledge of the patient. (4) In no case should the physican permit himself to substitute an operation for the one proposed by him. Should it be urged by the patient or those having

legal authority to act for her, provided the doctor considers such an operation dangerous or inopportune? The refusal to accept his intervention under the conditions proposed by him, relieves him of all obligation and of all responsibility as to the consequences of his refusal to act. Humanity alone should make it a duty for him to intervene.

**Conservative Surgery on the Adnexa.**—In discussing the relative value of this method of dealing with lesions of the adnexa, Hector Treub (Annals of Gyn., May, 1903) remarks that the danger of death from operation should not be more than two per cent. One cannot always be sure of affording the patient a complete cure of the trouble for which the operation was performed, so that there is a good possibility that a secondary operation, radical in character, may have to be performed some later period. Moreover, there is no way to foretell that the operation may not produce a new malady in the shape of a precocious menopause. In salpingo-oophoritis the so-called medical treatment is all that is necessary in a goodly proportion of the cases. If the medical treatment has been insufficient or contra-indicated, a radical operation should never be done at the outset, no matter what the conditions may be. Posterior colpotomy should always be the first step in the operative procedures. When by this means one has found that there is a tuberculous condition to deal with a hysterectomy may be readily performed. Where there is a stubborn hydrosalpinx after repeated colpotomy, and which necessitates other intervention, and in the case where one is going to try to remedy sterility in women, conservative abdominal operations (resection, salpingotomy, salpingo-oophorosydesis) are indicated. Salpingorraphy should be reserved as an accessory operation during the performance of a laparotomy performed for no matter what other indication.

**The Treatment of Retroversio Uteri.**—The most excellent treatment of this subject in a paper by Dr. Figuiera, of Nice, is analyzed by M. Morisette (La Gynécologie, June, 1903). Taking up the condition in pregnant and non-pregnant, the following are the conclusions of the author as to the proper method of treatment: (1) Curative treatment of retrodeviation of the uterus favors fecundation with women who have been sterile; (2) in recent retrodeviations, where the uterus is freely movable, the employment of pessaries may be most successful in the production of a cure of the trouble. The period of genital involution is truly the psychological period of the pessary. (3) In women with intact peronea in the absence of lesions of the adnexa, the Alexander operation is the one of choice. Where there are adhesions of the adnexa, laparotomy is indicated, followed by abdominal fixation and transfixion of the round ligaments. (4) In multiparæ who have torn perineums the abdominal fixation should be supplemented by plastic operations upon the cervix, vagina and perineum. This is the combined treatment of M. Doleris (1887-88.) In retrodisplacements of the gravid uterus manual replacement should be performed as soon as the condition is recognized. If this is not permissible, one should do celiotomy and shorten the round ligaments intra-abdominally, and there will result a direct and definite cure of the deformity.

## GENITO-URINARY AND SKIN DISEASES.

**New Methods in Treating Hydrocele.**—In an article dealing with the diagnosis and treatment of hydrocele, F. D. Roldán (Rev. de Med. y Cir. de la Habana, No. 10, 1903) describes an apparatus devised by him for the introduction of medicinal fluids into the sac after evacuation of the contents of a hydrocele. This apparatus is composed of three parts: A gutta percha canula which is adaptable to any trocar, a graduated glass vessel with a capacity of about 8 ounces and a vulcanized rubber tube 13 inches long connecting canula and vessel. With this apparatus a variety of maneuvers may be executed without removal of the canula from the tumor. Its advantatges may best be appreciated by a description of the author's method of procedure after evacuation of the tumor. The canula being inserted, from 1¼ to 2 ounces of a 1-in-100 solution of cocaine is poured into the glass graduate and by raising the latter, the fluid is made to flow into the sac. After two minutes, this is withdrawn by inverting and carrying the vessel below the level of the tumor. The vessel is next raised and into it is poured tincture of iodine, which is in turn allowed to flow into the sac by carrying the graduate above the tumor. This fluid is retained for three to four minutes, when it is syphoned out by inverting and lowering the vessel. The sac is then thoroughly washed out with sterilized water, which has been poured into the graduate, by alternately raising and lowering the vessel. A new method of closing the wound made in the radical treatment of hydrocele has also been devised by the author. The details of this procedure are seen at a glance in the illustrations accompanying the article, and to this the reader is referred. Suffice it to say that two rows of continuous sutures are used; one for the vaginal sheath, the other for the skin; and by an ingenious arrangement both may be removed simultaneously and without pain after healing has taken place.

**Epidural Injections in Genito-Urinary Diseases.**—Epidural injections, *i.e.*, injections between the periosteum of the vertebræ and the dura mater in the sacral region, constitute a new and apparently very successful method of treating functional diseases of the genito-urinary tract. A. Strauss (Münch. med. Woch., July 14, 1903) employs a solution consisting of cocaine muriate gr. $\frac{1}{6}$ (0.01), sodium chloride ʒiij (0.2), aq. destill ad. ʒiij (100.0), to which are added 2 drops of a 5-per-cent. solution of carbolic acid. In repeated doses of 1¼ to 7½ drams (5 to 30 cubic cures) much improvement was accomplished in enuresis nocturna, acquired incontinency, neuropathic polyuria, impotency and spermatorrhea and sexual neurasthenia. Untoward symptoms do not occur though sometimes the patients complain of a sensation of pressure in the lower spine which rapidly disappears with rest. For syphilis a 2-per-cent. solution of sublimate was used every second day or a 10-per-cent. solution of salicylate of mercury in liquid paraffin twice weekly; contrasted with the intramuscular method the reaction was, however, more severe, so that the latter is to be preferred for dispensary use. It is possible that in the cerebral and spinal manifestations of lues, this form of giving mercury has a great future provided salts that are better tolerated are employed.

## NEUROLOGY.

**Tabes and Marriage.**—A statistical article based upon a study of 240 tabetics and dealing with the influence of tabes upon fecundity and the health of the offspring in marriages in which one parent was afflicted with locomotor ataxia, is presented by A. Pitres (Jour. de Méd. de Bordeaux, July 12, 1903). The 31 celibates of this number are dismissed by the author without comment. The issue of the remaining 209 amounted to 483 children; of whom 197 were still-born or died in the early months and 286 survived; making an average of 2.31 births to each couple, with but 1.36 living children. Carrying the analysis further, the author states that of the 209 marriages, 42 or 20 per cent. were absolutely sterile, 32 or 15 per cent. resulted in still-births

or death shortly after birth; while in the remaining 135 or 60 per cent. there were living children in the relatively high proportion of 2.11 per family. The high mortality seen in the offspring of tabetics, the author believes, is attributable to the antecedent infection rather than indirectly to tabes; and this infection is, in the majority of cases, syphilitic. He cites figures which go to show that the mortality of children born before development of tabes in either parent was 44 per cent.; while those born after the appearance of tabes showed a mortality of but 28 per cent. This finding furnishes, in his opinion, additional proof of the statement made by Régis, to the effect that the offspring of tabetics have a better chance of life and health when born in the later stages of the parents' disease than at a period nearer to the antecedent infection. As to the outcome of his investigations looking to the determination of the influence of syphilis upon the mortality of tabetics' children, the following figures are quoted: Of 77 male subjects who had undoubtedly had syphilis, 187 children were born, of whom 33 per cent. were still-born or died in early infancy, and 67 per cent. survived. Of 34 who denied antecedent syphilis, 81 children were born, of whom 20 per cent. were still-born or died shortly after birth and 80 per cent. survived. With few exceptions, Pitres finds that the surviving children of tabetics are uninfluenced by the parents' disease; their physical and intellectual development proceeding normally as that of other children; and of the 286 children of tabetic parents, whom he kept under observation, many were alive at twenty years, and some had attained thirty and thirty-five years at the time of writing. In none did tabes or Friedreich's disease develop, neither was there evidence of any other nervous affection. None showed signs of physical or mental degeneracy, nor was the influence of syphilis apparent in any. On the other hand, some developed diseases independent of all hereditary influence; such as tuberculosis, rheumatic cardiopathies, etc. The great majority were, however, healthy in body and mind.

## EYE, EAR, NOSE AND THROAT.

**Erysipelas of the Larynx.**—Massei pointed out some time ago two varieties of erysipelas of the larynx: one where the general symptoms were prevalent, the other where the local symptoms were the most prominent. KONTCHERSKY (Prakt. Vratch., No. 25, 1903) presents an interesting case in which this subdivision is fully borne out by clinical experiences. The disease began in a woman, 49 years old, with pain in the throat, difficult deglutition, general malaise and headache. There was also considerable tenderness, congestion and swelling of the aryepiglottic ligaments. The condition did not yield to routine treatment and grew considerable worse. The patient became very hoarse, dyspneic, and suffered intense pains at every effort to swallow. Laryngoscopically the epiglottis was found so swollen as hardly to be recognized; it was impossible to make out the condition of the vocal cords. Under treatment with compresses, etc., some improvement was obtained and this continued for some time. However, with the local improvement there appeared gradually a condition that showed systemic infection—pain and feeling of heaviness in the head, tinnitus aurium, general weakness, inability to stand erect. The pulse, though normal in rate, was quite weak. From time to time attacks of fainting. In the course of a couple of weeks the condition grew still worse—the headache and noise in the ear became intolerable, and to these were also added hallucinations of sight and hearing of a very pronounced character. This continued for a week, and then disappeared without leaving a single trace. The author in discussing this case leans to the view that the affection was one of a general and not of a purely local nature; and it must have been of an erysipelatous character, because of the rapid and enormous swelling of the epiglottis, as well as the presence of a gray exudate, which disappeared, however, in the course of one day, leaving a marked erosion, which lasted for quite some time. The course of the disease after the disappearance of the local symptoms, mental dulness, hallucinations of sight and hearing, point to some systemic infection similar to that observed in typhoid, grippe and erysipelas. According to Massei primary erysipelas of the larynx is not to be diagnosed necessarily from the presence of cutaneous erysipelas anywhere else as it may appear without the latter. When Senator, in 1888, delivered an address on the so-called primary phlegmar of the pharynx Virchow pointed out that this was not an independent disease but a septic affection often in connection with puerperal sepsis, while Guttman has called attention to its similarity to an erysipelatous process. The author also mentions the general prevalence of erysipelas in the locality where the patient lived as well as the surrounding unhygienic condition that would still strongly substantiate his view as to the erysipelatous character of the case in question.

**Embolism of Central Artery of Retina Following Paraffin Injection Into Nose.**—A careful review of the literature reveals the fact that serious complications following the supposedly harmless injection of paraffin are not very infrequent. L. M. HURD and W. A. HOLDEN (Med. Rec., July 11, 1903) report an interesting case in which sudden blindness of one eye occurred a few minutes after such an injection for the improvement of the appearance of a nose after two previous successful injections had been made upon the same patient. A little ecchymosis appeared about the end of the nose indicating that a vein had been punctured. An immediate examination of the eye showed that the inferior branch of the arteria centralis was bloodless and the superior branch nearly so. An attempt was made to dislodge the embolus and force it forward into one of the branches. To accomplish this the heart was stimulated and the peripheral vessels dilated. The eyeball was pressed back into the orbit as far as possible to completely empty the ocular vessels and then by suddenly releasing it, it was hoped that the embolus might be drawn on by suction. This was unsuccessful and there was no subsequent improvement in the vision of that eye. It is, of course, difficult to explain how an embolus could get from a systemic vein into the central artery without being caught in the capillaries of the pulmonary circulation.

## THERAPEUTICS.

**Detection of Phosphorus in Oil.**—It is a well-known fact that oils containing small amounts of phosphorus, such as are used for internal administration, rapidly lose their efficacy when exposed to air and light, owing to oxidation. A simple method to estimate the amount of phosphorus, such as is given by W. STRAUB (Münch. med. Woch., July 7, 1903) is therefore welcome. Ten cubic centimeters of the oil are simply shaken with five cubic centimeters of a five-per-cent. solution of copper sulphate. A light brown to black discoloration, owing to formation of cuprous phosphate, will result. Somewhat later all the phosphorus will pass over into the aqueous part of the mixture as phosphoric acid, which can be determined voluntarily in the usual way, if the estimation by means of the depth of color is considered too inaccurate. A solution with only 0.0025 per cent. still gives an appreciable reaction, while the officinal oil of phosphorus gives a distinct brown discoloration after three to five minutes.

# The Medical News.

*A WEEKLY JOURNAL*

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, AUGUST 22, 1903.

## THE MEDICAL STUDENT IN THE UNITED STATES.

The *Journal of the American Medical Association* has just published (Aug. 15, 1903) its third annual Educational Number and it is a noteworthy and commendable undertaking.

Among other features discussed, that on the opportunities for medical education is naturally one of the most interesting and the figures given are well worthy of presenting. They say that the number of medical students in the United States for the year ending June 30, 1903, was 27,615. Of this number 24,930 were at the regular schools, 1,498 at the homeopathic, 848 at the eclectic and 339 at the physio-medical and nondescript schools. There was an increase in the attendance at the regular schools of 52 over last year, and an increase of 1,094 over the year previous—1901. In the homeopathic schools there was a decrease of 119 below that of 1902, and a decrease of 185 since 1901. The eclectics have increased in the number registered. This past year there were 848 registered, against 765 of the preceding year, and 664 in 1901, showing an increase of 83 over 1902, and 184 over 1901. Those in attendance at the physio-medical and nondescript schools numbered 339, an increase of 98 over last year, and 115 over 1901. The comparative table that they present is as follows:

TABLE OF MEDICAL COLLEGE ATTENDANCE.

| Year. | Regular. | Homeopathic. | Eclectic. | Physio-Med. and Nondescript. | Total. |
|---|---|---|---|---|---|
| 1880 . . . | 9,776 | 1,220 | 830 | . . . | 11,826 |
| 1890 . . . | 13,521 | 1,164 | 719 | . . . | 15,404 |
| 1900 . . . | 22,710 | 1,909 | 552 | . . . | 25,171 |
| 1901 . . . | 23,840 | 1,683 | 664 | 224 | 26,417 |
| 1902 . . . | 24,878 | 1,617 | 765 | 241 | 27,501 |
| 1903 . . . | 24,930 | 1,498 | 848 | 339 | 27,615 |

Speaking of graduates, they show that the total number of graduates in medicine for the year ending June 30, 1903, was 5,698, an increase of 669 over the preceding year. This is an increase of only 254 over the number of graduates for the year ending June 30, 1901. The decrease in the number of graduates in 1902 is assigned by the editor to the increased length of course of study and increased requirements by State boards. This decrease was considered by Dr. Simmons, in 1902, as only temporary, which is proving to be true. However, the normal condition as regards the number of graduates to the number of students registered has probably not yet been reached, for a very large number of the medical schools adopted the four years' course during the last three years. The statistics on this point are as follows:

TABLE OF MEDICAL COLLEGE GRADUATES.

| Year. | Regular. | Homeopathic. | Eclectic. | Physio-Med. and Nondescript. | Total. |
|---|---|---|---|---|---|
| 1880 . . . | 2,673 | 380 | 188 | . . | 3,241 |
| 1890 . . . | 3,853 | 380 | 221 | . . | 4,454 |
| 1900 . . . | 4,715 | 413 | 86 | . . | 5,214 |
| 1901 . . . | 4,879 | 387 | 148 | 30 | 5,444 |
| 1902 . . . | 4,498 | 336 | 138 | 27 | 4,999 |
| 1903 . . . | 5,088 | 420 | 149 | 41 | 5,698 |

It is a pleasure to note that the number of medical colleges has decreased. The total number of medical colleges in the United States which grant the degree of M.D. is 154. Of these 121 are regular, 19 homeopathic, 10 eclectic, 3 physio-medical, and 1, the National Medical College of Chicago, nondescript, this institution advertising to teach not only according to the tenets of the four "schools" mentioned, but also osteopathy. In addition to the above, there are three schools which give instruction in the first two years' work. In other words, there are 157 institutions devoted to teaching medicine in the United States.

The number of medical schools, including for comparison the same statistics for the years 1880, 1890 and 1900, is given as follows:

COMPARATIVE TABLE OF MEDICAL COLLEGES.

| Year. | Regular. | Homeopathic. | Eclectic. | Physio-Med. and Nondescript. | Total. |
|---|---|---|---|---|---|
| 1880 . . . | 72 | 12 | 6 | . . | 90 |
| 1890 . . . | 93 | 14 | 9 | . . | 116 |
| 1900 . . . | 121 | 22 | 8 | . . | 151 |
| 1901 . . . | 124 | 21 | 10 | 4 | 159 |
| 1902 . . . | 121 | 20 | 10 | 4 | 155 |
| 1903 . . . | 121 | 19 | 10 | 4 | 154 |

An important and far-reaching feature of this statistical study concerns the location of colleges and their clinical advantages, and the ratio of schools to the population. The figures gathered by Dr. Simmons are worthy of the most careful consideration. He says that it is acknowledged by all who have given thought to the subject that a town of less than 50,000 inhabitants cannot except under unusual circumstances, supply the clinical advantages that third and fourth-year students require. Yet the fact is there are thirty medical colleges located in towns of less than 50,000 that confer the degree of M.D. Ten of these schools are in towns of between 30,000 and 40,000, two in towns of between 20,000 and 30,000, six in towns of between 10,000 and 20,000, and nine in towns of less than 10,000.

Concerning the ratio of schools to population he shows that there are 14 cities containing 4 or more schools each, and these cities contain 84 of the 154 schools. Below is a table of these cities, with population, number of schools and ratio of population to each school. The population in each instance is based on the census report for 1900. It is quite probable that the population of all of these cities has increased, but, if so, the relative increase is possibly about the same. It will be noticed that New York has the fewest medical schools in proportion to its population, and that Chicago has the distinction of having the largest number of medical schools of any city in the United States.

TABLE OF RATIO OF COLLEGES TO SIZE OF CITIES.

| City. | Population. | Number of Schools. | Ratio of Pop. To Each School. |
|---|---|---|---|
| Dallas | 42,638 | 4 | 10,659 |
| Nashville | 80,805 | 5 | 16,173 |
| Kansas City | 163,752 | 6 | 27,292 |
| Louisville | 204,731 | 7 | 29,247 |
| Indianapolis | 169,164 | 4 | 42,291 |
| Baltimore | 508,957 | 8 | 63,619 |
| San Francisco | 342,782 | 5 | 68,556 |
| Washington | 278,718 | 4 | 69,679 |
| Cincinnati | 325,902 | 4 | 81,475 |
| St. Louis | 575,238 | 6 | 95,873 |
| Chicago | 1,698,575 | 14 | 121,326 |
| Boston | 560,892 | 4 | 140,223 |
| Philadelphia | 1,293,697 | 6 | 215,616 |
| New York | 3,437,202 | 7 | 491,029 |

A complete discussion of this most elaborate study would lead to many interesting conclusions. One that strikes the practitioner concerned in the higher education of the young medical student is that the element of ignorance of his opportunities is no longer a bar to the best. The medical student of the future chooses his place of study with his eyes wide open to what there is to be found in the country. May this be the means of elevating the entire mass of institutions in their laudable competition to give the best.

## A NEW ERA IN CHLOROFORM ADMINISTRATION.

The stubble of a luxuriant corn-field is troublesome to uproot. It taxes the farmer's efforts in direct proportion to the strength and length of the stalk. It may or may not have borne good fruit. So, precisely, it is with the field of anesthetics.

Therefore, all laudable commendation upon the efforts of the chloroform committee of the British Medical Association! Its second report—1902-1903—brings the cheering news that definite progress is being made.

It cannot be amiss to glance at some of the stubble which this worthy body has encountered and which is pointed out not in any spirit of criticism, but simply to show how much chaff and how little grain constitutes the crop of our knowledge, even up to the present moment. Of diverse, divergent and dissenting opinions we have indeed a full crop.

The latest and undoubtedly one of the very highest American authorities is Brewer's Text-book of Surgery. It is crisp from the press and pregnant with the new and vigorous thought of its maker. In speaking of the administration of chloroform it says that the drug may be given upon a folded handkerchief held "two or three inches above the mouth to allow *a generous admixture of air*. . . . An effort should be made to give *ten per cent. of the vapor of chloroform* and ninety per cent. of air." Very distinct recognition is given the fact that danger arises from a too high concentration of the vapor, suddenly administered.

In Park's Surgery it is stated in italics that chloroform should always be given with ninety-five per cent. of air.

In the American Text-book of Surgery the administration of chloroform is described as follows: "A towel may be placed over the patient's mouth and be kept moistened by chloroform, drop by drop, or about a half teaspoonful should be poured upon a napkin and held about an inch from the face. . . . Experiment has shown that the vapor is inhaled under the condition just stated in the strength of five-per-cent. admixture with air, which is a proper proportion."

The eminent English authors, Rose and Carless, state that, "Much controversy has arisen as to whether the heart is ever directly affected by the drug or whether the symptoms are not due to

primary failure of the respiration. The experimental evidence on the subject is of a very conflicting nature and it is impossible as yet to consider the question solved. The Scotch school, headed by Syme and Lister, maintains that the breathing alone need be watched. Many surgeons and anesthetists oppose this view. . . . The chief points to be attended to are regularity of dose and full admixture with air so that not more than *four per cent.* of the vapor is inhaled."

Among these standard authors there is to be noted a variation from about ten to about two per cent. All recognize the importance of free dilution with air. None are prepared to instruct in any method which shall determine the percentage in more than a haphazard fashion.

We have passed the transitional stage, thanks to the efforts of the members of the committee of the British Medical Association, and should soon be in possession of all practical data to utilize the new methods and the apparatus desired, and methods endorsed by Sir Victor Horsley are not to be passed over lightly.

From a practical standpoint *the* conclusion in this report is that chloroform should be administered in quantities varying between 0.5 per cent. and two per cent. "An average of one per cent. is sufficient for the induction and maintenance of narcosis." The chloroform should be given through an inhaler so constructed that the delivery shall be continuous and shall be indicated on a percentage scale.

Although in this country the giving of ether has received a tremendous impetus since the multiplication and general adoption of the nitrous-oxide-ether inhaler, because this instrument has almost entirely done away with the disagreeable elements in ether taking, the field is not yet closed to chloroform.

Those who read the report will find a long list of operations which were successfully carried on with the aid of Mr. Vernon Harcourt's apparatus, in which the air to be inspired derives its chloroform vapor from being drawn over the surface of the drug. This differs from Dr. Junker's apparatus, in that his method consists in blowing air *through* the chloroform. The heat rendered latent by this procedure introduces a variation in the quantity of gas taken by the air. By instruments of exact measurements the modes of administration of anesthetics have been brought out of chaos to the precision required of a precise age. We congratulate the chloroform commission and its report.

## ECHOES AND NEWS.

### NEW YORK.

**The Eye and Ear Infirmary.**—Dr. Richard A. Derby, of the Board of Directors of the New York Eye and Ear Infirmary, announces that the gift of the late William C. Schermerhorn to the infirmary of a building to be devoted solely to the treatment of diseases of the eye has been supplemented by a gift from the daughters of Mr. Schermerhorn of money for the equipment of the building with all the necessary surgical appliances and furnishings.

**Barber Regulations.**—Copies of Section 179 of the revised Sanitary Code, which includes the new regulations for barbers, were sent out last week. There are eleven of these rules. Here they are: Barbers must wash hands thoroughly with soap and hot water before attending any person.

No alum or other astringent shall be used in stick form. If used at all, to stop flow of blood, it must be applied in powdered form.

The use of powder puffs is prohibited.

No towel shall be used for more than one person without being washed.

The use of sponges is prohibited.

Mugs and shaving brushes shall be thoroughly washed after use on each person.

Combs, razors, clippers and scissors shall be thoroughly cleansed by dipping in boiling water or other germicide after every separate use thereof.

No barber, unless he is a licensed physician, shall prescribe for any skin disease.

Floors must be swept or mopped every day and all furniture and woodwork kept free from dust.

Hot and cold water must be provided.

There is no rule to prevent a barber from sticking his thumb in a man's jaw to pull the surface smooth for shaving, but President Lederle, of the Health Board, says that it is understood that this practice must be discontinued. The regulations also advise customers to have their own brushes, combs, razors and shaving cup. The rules are to be hung in a conspicuous place in every barber shop, and violators are threatened with severe punishment.

**Obituary.**—Dr. John Gleises, of New York, who was spending the summer at Brookside, died August 14. He was fifty years old and leaves two sons.

### PHILADELPHIA.

**Chickenpox a Notifiable Disease.**—Chickenpox has been placed on the list of diseases that physicians must report to the Board of Health. On numerous occasions during the present prevalence of smallpox, physicians summoned before the Board for failure to report the names of patients suffering from that disease, have excused themselves with the plea that their diagnosis was chickenpox. In order to prevent this shielding of smallpox patients, the Board has decided that chickenpox, as well as smallpox, must be reported.

**Results of the Ball Park Accident.**—A general inspection of all places of amusement, including theaters and outdoor resorts, has been begun by the building inspectors. The larger part of the outdoor stand at the Philadelphia Ball Park will have to be rebuilt before games are allowed. As result of the recent accident twelve people have died. Donations are being made to the Samaritan and St. Luke's hospitals to aid in replenishing supplies which were all used in caring for those wounded at the accident.

**Woman's Hospital.**—Plans for the new Woman's Hospital have been filed. It is to be a six-story building of granite, limestone, and terra cotta.

## CHICAGO.

**Chicago's Milk Supply Improving.**—Out of 760 samples of milk and cream analyzed in the Laboratory during the week 60 were found below grade. Among these 760 samples from all sources there were 112 taken at the trains—before the milk had come into the possession of the city dealer. Out of these 112 samples four were found below the standard of butter fat and 40 below the standard of total solids. Thus, while the per cent. of samples below grade from all sources was only 7.9 per cent. the proportion of samples below grade in the milk and cream direct from the farmer, and before the wicked city dealer had an opportunity to tamper with it, was nearly 40 (39.2) per cent. These figures are the sufficient refutation of an assertion made with increasing frequency since the enforcement of the new milk ordinance has begun to disclose the principal and primary offenders. If the State Pure Food Commission will take care of the farmers the Bureau of Milk Inspection will continue its care of the city dealers.

**Typhoid Fever Statistics.**—Although the anticipated increase of typhoid fever has resulted to quite as great an extent as was feared (from the pollution of the city water several weeks since), it has not yet been reflected in the mortality. Nearly all hospitals report an increase of cases—the net figures being about 28 per cent. greater than for the previous week. But the typhoid deaths reported are decreasing.—only 8 during the week as against 11 the week before and 45 in the corresponding week of last year. Since July 1 the total typhoid deaths reported have been only 55 as compared with 133 between July 1 and August 16, 1902. With a higher temperature and the return of summer vacationists, however, the typhoid deaths will undoubtedly increase.

**Smallpox on the Increase.**—Ten new cases of smallpox were discovered and removed to the Isolation Hospital. Dr. Spalding, the Chief Medical Inspector, again dwells upon the fact that none of these had ever been vaccinated and that seven of the number were children ranging in age from two months to six years. Two of these died Saturday morning. "Why," asked Dr. Spalding, "shouldn't the law require parents to have their children vaccinated before the age of six years? Certainly these babies have as much right to live as children at the school age. The law requiring all children to be vaccinated before entering the schools has protected absolutely every school child from smallpox for a period of more than ten years. No vaccinated schoolchild has ever had smallpox. There should be a law passed without delay requiring parents under penalty to have their children vaccinated before the age of six months."

**Mortality Statistics.**—The week's mortality rate is again remarkably low. The 483 total deaths reported represent an annual rate of only 13.36 per 1,000 of population. This is 6 per cent. less than the rate of the previous week; 8.7 per cent. less than that of the corresponding week of last year and nearly one-fifth—18.3 per cent.—less than the average August rate of the previous decade.

## GENERAL.

**Yellow Fever in Texas.**—In view of the appearance of yellow fever at Victoria, Tex., about 70 miles from Monterey, on the line of the Monterey & Gulf Railway, the quarantine established here has been made more rigorous by the appointment of an additional force of guards by the State authorities. Both the State and Marine Hospital Service physicians are at present at Monterey investigating the rumor to the effect that yellow fever exists in that vicinity. The consensus of opinion is that a quarantine against Monterey will be established, and should such action be taken, it would mean a temporary tie-up of railway traffic.

**The Prevention of Malaria in Hongkong.**—A series of reports and minutes written between the years 1900 and 1903, says the *British Medical Journal*, by Dr. Thompson, of Hongkong, shows some of the results obtained by that colony in its campaign against mosquitoes. Dr. Thompson on his return from England in 1900 began a research into the prevalence of mosquitoes and malaria in the colony of Hongkong and in the new territory, and, after a careful examination of those districts, made a plan on which were depicted the various areas where mosquitoes bred. Many places were found suitable for the breeding of the insects, and of those the nullahs were the worst, one especially above Ripon Terrace passing the end of Nethersole Hospital being heavily infected with mosquito larvæ. Other areas, quite close to the Government Civil Hospital, the author thinks supplied *Anopheles* mosquitoes for the transmission of malaria from person to person in the hospital, and this is quite consistent with the conditions so often noted in other tropical countries. A large number of external examinations of mosquitoes showed that insects of the genus *Culex* greatly predominated, though *Anopheles* were also not uncommon. No note is made as to the numbers of those infected with malarial parasites, and this in the light of the India work on this subject is unfortunate. As a result of the researches into the breeding areas, a series of recommendations similar to those advocated by Major Ross in Africa, and by other observers in different parts of the world, were proposed. A second visit to the areas in 1902 showed that there was a distinct improvement, and further work was advised still to better their condition. In 1903 another survey again showed fewer mosquitoes, but here it may be noted that Dr. Thompson states that the measures adopted have only been temporary, and to be successful must be continuous till the nullahs are properly drained. It is a pity that no mention is made of any reduction or otherwise in the prevalence of malaria as a result of those measures, and it would be interesting in the future to have this point investigated. But Rome was not built in a day, and Hongkong is to be congratulated on what it has already done, and the hope may be expressed that it may go on energetically and do much more.

**Oysters and Typhoid Fever**—Dr. Bulstrode's official report on the oysterborne outbreaks of enteric fever which followed certain mayoral banquets last year, although anticipated by full reports by local medical officers of health, will be read, says the *British Medical Journal*, with great interest, if for no other reason because it coordinates the particulars contained in previous accounts, and gives a complete survey of the evidence on the strength of which these outbreaks were attributed to contaminated oysters from Emsworth. The title of Dr. Bulstrode's report is eminently cautious. It deals with "alleged" oysterborne enteric fever. The conclusion of the matter in the report is almost equally cautious, as will be seen from the following quotation (the italics are ours): "The foregoing narrative of facts would *seem* to establish the strongest possible *presumption* that oysters which had been deposited for a time at Emsworth have caused the outbreak of enteric fever and other illness which

followed the mayoral banquets on November 10 at Winchester and Southampton. A perusal of Dr. Bulstrode's admirable account of these outbreaks would, we venture to think, justify a more confident expression of opinion; and as this is a matter on which urgent administrative action and not merely an academical decision depends, and as in preventive medicine mathematical demonstrations of causative relationships are seldom if ever attainable, the words "*seem*" and "*appear*" which recur in the statement of conclusions in the report might probably have been omitted without sacrifice to accuracy, and with considerable practical gain. That this is so is shown by Dr. Bulstrode's own summary of the facts. Two mayoral banquets occurred on the same day in separate towns several miles apart. In connection with each banquet similar illnesses occurred, attacking approximately the same percentage of guests, and at corresponding intervals. At both banquets those who did not partake of oysters escaped, and all the guests who acquired enteric fever, and approximately all who suffered from other illness did partake of oysters. The oysters in question constituted the only article of food which was common to the guests attacked; and these oysters were all derived directly from the same source. Furthermore, oysters from the same source were at the same time, and in other places, proving themselves competent causes of enteric fever; and, we may add, these oysters were shown to be liable to serious contamination by sewage. The incidence of sickness on those who were guests at the two banquets is an interesting point. At Winchester 62 out of 134 guests suffered from some form of illness. Only two of these did not eat oysters. Ten of the guests had enteric fever, and all these had oysters. At Southampton there were 132 guests. Of these 55 became ill, out of which number 54 took oysters; 11 acquired enteric fever, all of whom took oysters. Dr. Bulstrode's remarks on the importance of epidemiological study of the origin of these outbreaks, and on the undesirability of trusting to bacteriological evidence alone, are eminently judicious. The whole report is an excellent example of careful and exhaustive inquiry, which may serve as a model to other investigators."

**Patent Medicines in Germany.**—The Federal Council of the German Empire, says the *British Medical Journal*, has drawn up a code of regulations regarding the sale of patent medicines in Germany, and has requested the Governments of the several States to issue orders, on the basis of its proposals, to come into force on January 1 next. The State of Hamburg has already acceded to this request. Prussia will shortly do so, and the other Federal States are likely to follow suit. Various well-known "panaceas" are said to be mentioned in the regulations among those which are to be prohibited.

**The Medical Profession in France.**—The *British Medical Journal* reports the case of a French doctor who was brought before a police court recently and sentenced to six months' imprisonment for petty larceny. When asked what had driven him to theft his reply was, "Hunger." He was dealt with as a first offender, and his friends have, we are pleased to say, established him in a respectable practice in a small town. The case has been used by the *Temps* and other newspapers as a text for disquisitions on the overcrowding of the learned professions in France. France has already, it is pointed out, too many doctors. Some statistics lately published by M. de Lavarenne show very clearly that this is the case. During the twenty-five years, 1876 to 1901, the date of the last medical census published, the number of doctors and *officers de santé* increased from 14,376 to 17,108. This increase was altogether disproportionate to the growth of population, for while in 1876 the ratio of practitioners to people was 2.90 per 10,000, in 1901 it was 4.08. These figures are still more instructive if we examine the distribution of practitioners throughout the country. In certain regions, especially in the departments of the Basses Alpes, Aveyron, Cantal, Charente, Corrèze, Creuse, Dordogne, Lot et Garonne, Haute Savoie, Tarn et Garonne, which have been greatly impoverished by a series of agricultural crises, the number of practitioners has diminished. On the other hand, in certain prosperous departments the number has greatly increased. Thus in the Bouches du Rhône there were 434 doctors in 1901 as against 370 in 1876; in the Nord 656 as against 456; in the Seine Inférieure 531 as against 412; in Seine et Oise 343 as against 244. The increase shown by these figures is very considerable, but in the Seine department it is far greater. While in 1876 there were 1,606 practitioners, in 1901 there were 3,281, the number having doubled itself in the twenty-five years. Of the 17,108 doctors 9,221 practised in rural districts having a total population of 27,595,528, while there were 7,887 in towns with an aggregate population of 11,366,417. In the towns themselves the distribution of practitioners was very unequal. Paris had 2,892 doctors for its 2,714,068 inhabitants, a ratio of 10.65 per 10,000. The cities of 100,000 to 492,000 inhabitants, with an aggregate population of 2,636,032, had among them 1,875 practitioners, a ratio of 7.4 per 10,000. On the other hand towns of 30,000 to 100,000 inhabitants which together made up a population equal to that of Paris had no more than 1,487 doctors, that is to say, 5.47 per 10,000. The proportion became less as the population of towns diminished. Thus those of 20,000 to 30,000 inhabitants, having an aggregate population of 1,297,058 had 635 practitioners—4.89 per 10,000; and the towns of 10,000 to 20,000 only had among them 1,010 doctors—5.08 per 10,000. In the country the average proportion of practitioners to populations was 3, while in Paris it was 11 to 10,000. From a recent unofficial estimate we learn that the total number of medical practitioners in France in the present year of grace is 18,735, being an increase of 1,627 as compared with 1901.

**Deaths in Europe.**—Among the members of the medical profession in foreign countries who have recently died are Dr. Oliveira Monteiro, Professor of Medicine in the Medical School of Oporto; Dr. Vacher, Mayor of Treignac, formerly Member of the French Chamber of Deputies, author of numerous works dealing with social economy and hygiene, aged seventy-one years; Dr. Bele, sometime Senior Surgeon to the Hospital of Maus, aged eighty-two years; Dr. Rudolf Trzebitzki, Professor of Surgery in the University of Cracow, aged forty-one years; and Dr. Julien Bouglé, Surgeon to the Paris hospitals, and one of the editors of the Archives Générales de Medecine, aged thirty-five years.

**The Continental Anglo-American Medical Society.**—The annual luncheon of the society was held in Swansea, at the Hôtel Metropole, on Thursday, July 30th, and was very successful in every way. Dr. Freeman (San Remo) occupied the chair and twenty-seven members and their guests were present, including Dr. T. D. Griffiths (the President of the Association), Dr. Frederick Roberts, Mr. Mayo Robson, Mr. Walter Whitehead, Mr. Ward Cousins, Mr. Arbuthnot Lane, Mr. Edmund Owen, Sir Patrick Manson, Professor Adami, Dr. F. Burghard, Mr.

Sheen, Professor Herman Senator and Dr. Reinhold Ledermann (Berlin), Dr. H. D. Rolleston, Mr. C. D. Marshall, Dr. Dawson Williams, Dr. Irving Cameron (Toronto), Professor Albert Saundby, Dr. Logan Turner, Dr. Creasy, Dr. Leigh Canney (Assouan), Dr. Michael Foster (San Remo), Dr. Sandwith (Cairo), Dr. Samways (Mentone), and Dr. Leonard Robinson (Paris). The speeches were short, as Mr. Mayo Robson had to leave early to give the Address in Surgery. After the Chairman had proposed the usual loyal toasts, Mr. Edmund Owen, in happy speech proposed "The Health of the Society," and said what a good thing it was to learn to know each in this friendly way, and thus become acquainted with colleagues abroad, who would do the best for the patients and even attend to the embalming or burial if necessary. Dr. Sandwith, of Cairo, returned thanks and hoped the Society would see many of the present company at the International Congress of Tuberculosis to be held in Paris in October, 1904. Dr. Michael Foster proposed the health of the guests, to which Dr. Frederick Roberts replied, saying what pleasure it had given him to be present, and he hoped to make the acquaintance of the remaining one hundred members at the dinner in Paris in 1904, when the Society will be, so to speak, at home with their own chef. A vote of thanks to the chair terminated the most enjoyable meeting.

**American Association of Obstetricians and Gynecologists.**—The American Association of Obstetricians and Gynecologists will hold its sixteenth annual meeting in the Northwestern University Medical School Building, Chicago, Ill., Tuesday, Wednesday and Thursday, September 22, 23 and 24, 1903, under the presidency of Dr. Lehman H. Dunning, of Indianapolis. The Auditorium Hotel Annex has been selected for the headquarters of the association, the management of which should be addressed concerning rooms and rates. Dr. J. B. Murphy, Reliance Building, 100 State street, is the chairman of the committee of arrangements and will gladly furnish any information to members and guests upon application. Dr. Murphy also can be addressed, relating to accommodations, at the Auditorium Annex, or other hotels. The following list of papers has been offered: 1. President's address, by L. H. Dunning, Indianapolis; 2. Supravaginal Amputation for Fibroids, with report of cases, by H. E. Hayd, Buffalo; 3. Traumatic Rupture of Intestines Without External Marks of Violence, with report of cases, by Geo. S. Peck, Youngstown, O.; 4. Ectopic Pregnancy, H. D. Ingraham, Buffalo; 5. Relationship of the Colon to Abdominal Tumors, by J. F. Baldwin, Columbus; 6. Cysts of the Kidney Resembling Ovarian Tumors, with cases, by Rufus B. Hall, Cincinnati; 7. Total Extirpation of the Vagina for Carcinoma, by Charles G. Cumston, Boston; 8. Surgery of the Female Bladder and Urethra, by John B. Murphy, Chicago; 9. Surgery of the Ileocecal Valve for Non-malignant Disease, by N. Stone Scott, Cleveland; 10. The Curette in Postpartum Infections of the Uterus, by D. Tod Gilliam, Columbus; 11. The Use of Veratrum Viride in Surgical and Obstetrical Practice, by Chas. L. Bonifield, Cincinnati; 12. Should the Uterus and Ovaries be Removed in Cases of Double Pyosalpinx? by C. C. Frederick, Buffalo; 13. Placenta Previa, E. T. Abrams, Dollar Bay; 14. The Limitations of Cæsarean Section, by E. Gustav Zinke, Cincinnati; 15. Further Notes on Ovarian Grafting, by Robt. T. Morris, New York; 16. Conservative Surgical Treatment of the Uterine Adnexa, by A. P. Clarke, Cambridge; 17. The Value of Vaginal Cæsarean Section, M. Stamm, Fremont, O.; 18. Hysteria as a Result of Chronic Atrophic Parametritis; a Contribution to the Study of Nervous Disturbances, by W. A. Freund, Berlin; 19. Anesthesia in Abdominal Surgery, by J. J. Gurney Williams, Philadelphia; 20. The Technic of Gynecological Work, by A. Vander Veer, Albany; 21. Emergency Abdominal Surgery at the Patient's Home—a Demonstration, by W. G. Macdonald, Albany; 22. Discussion of Common Causes of Death Following Pelvic and Abdominal Operations, by Joseph Price, Philadelphia; 23. The Indications and Technic of Vaginal Drainage for Suppuration in the Pelvis, by A. Goldspohn, Chicago; 24. Intravaginal Elongation of the Cervix, by M. Rosenwasser, Cleveland; 25. Appendicitis, by Walter P. Manton, Detroit; 26. Chloroform in Labor, by Edwin Ricketts, Cincinnati; 27. Study of the Symptoms and Surgical Treatment of Intestinal Perforation in Typhoid Fever, by W. D. Haggard, Nashville; 28. Symptomatology of the Pelvic Musculature, by Hugo O. Pantzer, Indianapolis; 29. Palliative Treatment of Cancer of the Cervix, by Walter B. Chase, Brooklyn; 30. Abdominal Versus Vaginal Hysterectomy in Carcinoma Where the Radical Operation is Warranted, by John B. Deaver, Philadelphia; 31. Hysterectomy in Infectious Diseases of the Uterine Appendages, by H. C. Deaver, Philadelphia; 32. The Scope and Limitation of Myomectomy in the Treatment of Fibroid Tumors of the Uterus, by L. S. McMurtry, Louisville; 33. In Memoriam—William E. B. Davis, L. S. McMurtry, Louisville; 34. Penetrating Gunshot and Stab Wounds of the Abdomen, with report of cases, by John Young Brown, Jr., St. Louis; 35. Report of Abdominal Section During Pregnancy, by X. O. Werder, Pittsburg; 36. Shortening the Round Ligaments by the Blunt Hook Method, by H. W. Longyear, Detroit; 37. The Gilliam Operation; a clinical contribution, by Edward J. Ill, Newark; 38. Report of a Fourth Consecutive Successful Operation for Acute Perforated Gastric Ulcer, with General Infection of the Peritoneal Cavity, by Henry Howitt, Guelph, Ont.

During the meeting Dr. J. B. Murphy, by request, will hold a clinic, at which some demonstrations of special interest will be made. Dr. Macdonald will give a demonstration of Emergency Surgery at the Patient's Home, showing operator, assistants, nurses and equipment in full detail, immediately preceding Dr. Murphy's clinic. All members of the medical profession are cordially invited to attend the scientific sessions.

**He's Got It Reduced to a Science!**—He was a doctor of the advanced school. He laid his fingers on my pulse, and, with his watch in his hand, gave it a fair start and observed it carefully all of the way around.

"Strong, 74," he said, in a moment. Then he consulted a card that was covered with figures and continued: "That equals 63," and he placed the number on a slate. "Put out your tongue. Good! That is 14," he said.

"Inches?" I asked.

"How is your appetite?" he inquired, ignoring my question.

"Equal to the supply."

"That makes 204," he replied.

"Can't you reduce it a little?" I asked, but failed to get his attention.

"Cold feet?"

"Yes," I answered.

"Three," he said.

"No, 2," I replied, to correct him.

He set the three under the other figures. He then placed a thermometer in my mouth, which he afterward consulted in connection with the card.

"A good 198," he said.

"Impossible," I suggested, mildly.

He wrote down the 198 and asked if I had headaches.

"Sometimes, in the morning, after being kept late at the office," I answered.

"Four," he said.

"Isn't that rather low?" I asked.

"Do you smoke," he inquired.

"Yes."

"Ten," he replied.

"No, two for 10," I said.

He put down the 10.

"Do you sleep well," he asked.

"That depends upon the baby," I answered.

"We won't consider that," he said.

"You had better call it 980," I suggested.

He added together the figures that he had placed on the slate.

"That makes 496," he said.

"Is that the amount of the bill," I asked.

"Bill?" he replied. That is the number of the prescription. I want you to know that medicine with me is no longer an experiment, for I have reduced it to a mathematical certainty. Every sympton has its number, and the sum of these numbers indicates the medicine that is needed. I have worked for fifteen years in formulating my prescriptions and perfecting the treatment, but I have it now. Your bill is $10.

I understood that number, and left the office feeling relieved and deeply impressed by the doctor's learning.—*Harper's Bazar.*

**Some New Data Concerning Smallpox and Vaccination.**—Professor C. E. A. Winslow, of the Massachusetts Institute of Technology, in writing for Science, reviews Dr. Edwardes' recent work on "A Concise History of Smallpox and Vaccination in Europe," and draws some interesting conclusions of his own. He thinks the enforcement of State laws in this country requiring primary vaccination would be attended with difficulty because of certain factors in the process which it is difficult to eradicate. In the past disease was often transmitted by the "arm to arm" method, but now with our purified serum and careful scientific manipulation we have limited such transmission to erysipelas and tetanus, and these are quite often secondary infections due to somebody's meddlesome intervention. Still, such occurrences are frequent enough to make compulsory vaccination of doubtful success. The article says: "No one now supposes that a single vaccination affords absolute permanent protection, and with the increase of vaccination there must naturally come an increase of cases among the vaccinated. The experience of Leicester, on the other hand, is certainly of interest. It shows that under certain conditions the dangers of neglected vaccination may for a time be braved with impunity by a considerable portion of the community. This has been so far accomplished by prompt reporting and strict isolation of cases, and, according to the Chairman of the Public Health Committee of the town by the fact that a handful of the population, including the medical men, sanitary staff, smallpox nurses, etc., are as well vaccinated in Leicester as in any other town, so that a cordon of protected persons can at once be drawn around any case of smallpox which may occur." However, one should remember that there was some protection afforded to the inhabitants of Leicester by vaccination previous to the adverse agitation. In the epidemic of 1892-5 198 persons out of 358 attacked had been vaccinated some years before.

The article further says: "The objection made to the hospital statistics, namely, that the deaths of the unvaccinated class are unfairly increased by the inclusion of doubtful cases, and those who have been vaccinated but show no scars, can scarcely apply to the commission's analyses. It will not, at any rate, have much weight, except with those who, like Mr. Wallace, believe that 'in this matter of official and compulsory vaccination both doctors and Government officials, however highly placed, however eminent, however honorable, are yet utterly untrustworthy.' With regard to the smallpox occurring in persons once vaccinated, there are two points to notice. In the first place, the ratio of deaths to cases is far lower than among the unvaccinated. Thus at the Leipsic city hospital in 1870-2, 99 died among 139 unvaccinated cases, 116 died among 1,504 vaccinated cases, and none among 13 revaccinated cases. Creighton and Wallace object to these statistics on the ground that the death rate thus apparent among the unvaccinated is obviously too high, because 'in pre-vaccination times the death rate (18.8 per cent.) was almost the same as it is now in the vaccinated and unvaccinated together. A single vaccination then greatly reduces the probability of an attack of smallpox, postpones it to a later period of life, and renders it less dangerous if it does ensue. To insure absolute protection revaccination is required; and its efficacy is well indicated by the experience of the Prussian army. In addition, one single bit of evidence may be adduced which is more striking, perhaps, than all the rest, the statistics of nurses in smallpox hospitals. These figures are of special interest because we have here a fairly large class of persons whose condition as to vaccination is accurately known, and who are uniformly exposed to the contagion of the disease; and the experience of two such communities is quoted by Dr. Edwardes. 'During the epidemic of 1871 there were 110 persons engaged in the Homerton Fever Hospital in attendance on the smallpox sick; all these, with two exceptions, were revaccinated, and all but these two escaped smallpox. Of 734 nurses and attendants in the Metropolitan Asylums Board Hospitals, 79 were survivors from smallpox attack—they escaped infection; 645 were revaccinated on entrance —they all escaped; 10 were not revaccinated, and the whole 10 took smallpox.' If statistics ever proved anything those quoted above prove the protective influence of vaccination. If any fact in science is certain, it is certain that a successful vaccination absolutely prevents smallpox for a period of some seven to ten years, that after that period it renders the disease less fatal, and that its complete protective effect may be renewed by revaccination."

**A Municipal Milkshop.**—Dr. William Robertson, medical officer of health, of Leith, Scotland, writes on the subject of municipal milkshops in an article for the County and Municipal Record, which is copied in a current issue of the *Sanitarian*. In the course of his article Dr. Robertson records the following observations: "I have always held most decided views upon the milk supply of towns, and the more I learn of the little ways of cow feeders the more strongly do I feel the need there is for a greater uniformity of action by various sanitary authorities throughout the country. That this uniformity does not exist can be demonstrated by touring different districts. . . . The fact that thousands of infants are dependent upon milk for their sustenance is a strong argument in favor of raising the level of excellence of our milk supply. I do not mean to say that the milk as it comes from the byre is always bad. There may be, and often are, in-

stances where the milk is taken into a dirty house, in which filthy dishes and foul bottles are requisitioned to store the milk. . . . Three years ago I visited St. Helens, and described in the *Sanitary Journal* what I saw at the milk depot. So impressed was I with the common-sense and educative value of the scheme that I, literally speaking, put it into my pocket for future use. Liverpool, Ashton-under-Lyne, and Battersea have now adopted the principle of feeding infants, and at each place the movement has been a signal success. Leith, as is well known, boasts of a low general death rate, but I found that the mortality among infants was unduly high. This fact was brought prominently before the local authority, and I was asked to report fully on the whole subject, and to offer recommendations to reduce the death rate among infants. A subcommittee went very fully into the report, and gave the matter most sympathetic attention. The result was a unanimous recommendation that a milk depot ought to be started. I may say I had, some weeks before, visited Liverpool, where three depots are in operation, and was able to guide the committee upon a probable line of action. When the subcommittee's recommendation came up before the whole Town Council I anticipated a revolt against the apparent attempt to municipalize a milkshop, but a very much broader view of the question was taken, and the subcommittee's recommendation was carried without a dissentient voice. To cut a long story short, a shop was taken in a central part of the burgh, at a rental of £20, and the necessary apparatus ordered. In Liverpool the operations, as I have said, are carried on on a very large scale. In one of the depots there are three large departments—one for cleaning bottles and sterilizing the milk, another for storing the milk and bottles, and a third, the front part of the shop, where the baskets are sold. In Leith the depot consists of a front and back portion. In front is the sterilizer and the shelves on which are kept the prepared bottles and baskets. The rear portion of the depot, screened off from the front, is where the bottles are washed and stored. . . . To keep down any feeling of jealousy on the part of the local cow feeders, it is my intention to take milk from them in rotation, giving each a month's supply. And as time goes on I hope to establish agencies in different parts of the burgh, so that orders may be received for the sterile milk. I think the dairymen will assist me to carry this idea into effect. What I have said refers to what one might call a tentative scheme. The success of the Leith depot is practically assured, for the medical practitioners are in entire accord with the scheme; and when the medical officer of health can claim the general practitioners as allies he can go on with his work with a very light heart and cheery confidence. In conclusion, I would only add that the effect of a milk depot to provide sterile milk for infants can neither be felt nor appreciated in a month. One must wait until the educative influence of the depot has taken root. The points that seem to appeal to parents as the result of using sterile milk are—first, that they have now no worry in making up bottles; secondly, fretful infants enjoy a rest at night in place of squirming with flatulence and pain; and, thirdly, several mothers have declared that the vomiting which was common has now almost ceased."

**Financing Smallpox.**—The *Times* editorially comments as follows: "Getting the smallpox in one's home town and exploiting its eruptive and succeeding stages elsewhere at the expense of reluctant Samaritans who, like the 'flowers that bloom in the spring, tra-la,' have nothing to do with the case except what is forced on them as a matter of self-protection, is a proceeding which is now exciting considerable municipal and legal attention in Connecticut, occurrences of the sort having of late been rather frequent there. A mother and daughter living in Stamford visited the neighboring town of Norwalk a year or so ago, and while there blossomed forth with unmistakable stigmata of the disease. They were promptly taken in hand by the authorities, sequestered, and in the course of several weeks doctored into health and sent home. All this involved expense, the amount considerably exceeding a thousand dollars, and this the Norwalk Selectmen asked the Stamford Selectmen to pay. No attention was given to the requisition. It was received in silence, which in this case did not give a cent. But as time wore on it became the subject of increasing prolixity of correspondence between the cities, bringing the matter no nearer to a settlement. Stamford flatly said it wouldn't pay; Norwalk referred the matter to its Town Council, who looked into it with the penetrating eye of a magpie looking into the hollow end of a bone, and decided that it constituted a valid ground of action. A suit was therefore brought, and it will be argued as soon as the courts reconvene after their summer vacation. The case will, then, no doubt, be considered in all its legal and perhaps its moral and ethical bearings, affording a precedent to rule future ones as they may arise. They have cropped up quite frequently of late, particularly in the respected Commonwealth named, and it is quite time that some authoritative judicial decision concerning them should there be placed on record. Stamford has had its own experience of caring for cases originating elsewhere, and has spent considerable money in looking after them. Citizen George Francis Train came there awhile ago from his New York abode and proceeded to break out all over, like a branch of the red, red rose, as if he had deliberately timed his arrival to synchronize with that crisis. He didn't want to be sequestered, or treated, but they took him in hand all the same and expended $1,900 in bringing him around to his normal non-contagious condition. He had spent many years of his life, then descending into its wintry period not void of a withering picturesqueness, in vindicating the principle that the peanut was a sufficient cure for all bodily and many spiritual ills, and in pursuance of his mission had consumed large quantities of this trivial but nourishing subterrene growth on the open-air benches of Madison Square. Thither, as year followed year, the children and the sparrows flocked to see him. It involved a surrender of his theory to admit that any other treatment in any crisis was necessary, and he only submitted to it under protest. None the less some of the Stamford Selectmen think that the town has a good case against the metropolis for reimbursal of its outlay and favor its vigorous prosecution. In their opinion, New York has no right to unload her smallpox cases, in full or partial development, on neighboring towns; moreover, she is rich and can afford to pay. Probably we have not yet heard the last of it—if we are to pay doctors' and nurse's bills for anybody involved in like conditions. The spectacular citizen and ideologist named is as well worth it as another, and even the vigilant obstinacy of our present Controller ought to relax when the bill comes before him, if indeed that stage of the proceeding be ever reached. There seems a measure of inconsistency on the part of the Stamford authorities in refusing to pay Norwalk's bill while suing another town for

another one incurred under the same conditions. The best culinary authorities have always held to the principle that what was sauce for the goose was also suitable basting fluid for the gander, and if Stamford is bent on getting back what it has expended in this way to the point of going to law about it it is difficult to see how she can reasonably stand up against Norwalk's contention and refuse to liquidate all the items of the smallpox account between them."

**Genius and Eyestrain.**—A recent leading article in *The British Medical Journal,* from one who knew some of the men, is of interest. We give it in full: "Lawrence Sterne was, in the words of Sir Thomas Browne, 'knaved out of his grave,' and his body was recognized on a dissecting table at Cambridge. The fleshly garment of the author of *Tristram Shandy* was doubtless dealt with as the chance treasure trove of the resurrection man; the idea of anatomizing genius had not been conceived in his day. Though Dryden has said that 'great wits are sure to madness near allied,' the intimate connection between genius and disease does not seem to have been suspected till comparatively recent times. It is true that poetry is said to have been defined by the French medical philosopher, Cabanis, as a disease of the small intestine, but no one seems to have succeeded in verifying the reference. Nowadays genius is, in Tennyson's elegant phrase, 'ripped up like a pig,' or rather it is scientifically dissected. Great men are everywhere knaved out of their graves. Sir Thomas Browne himself has shared the common lot; Beethoven's ear, Gayarre's larynx, the skulls of Cromwell and Richelieu, to mention but a few, have been scrutinized, probed, and measured. A book has been written on Gambetta's brain; the bones of St. Cuthbert and St. Thomas of Canterbury have been the subjects of anatomopathological research. In default of material for dissection, medical commentaries are written on the infirmities of genius—on Cervantes's cardiac dropsy, on Swift's 'vertigo,' on Napoleon's epilepsy and the 'itch' which is said to have afflicted him, on St. Teresa's hysteria, on Jean Jacques Rousseau's genitourinary troubles, on the pathological phenomena noted or inferred or suspected in Columbus, Petrarch, Tasso, Schopenhauer, and Goethe. That interesting collection of literary necropsies, *La Chronique Medicale,* ably edited by Dr. Cabanès, is a mine of information as to the illnesses of celebrated persons. So great is the interest taken in the physical infirmities of genius—using that word in the widest sense—that an elaborate monograph was written by Dr. Toulouse on Zola's constitutional peculiarities during the life of that writer. It is scarcely fair, perhaps, to class Dr. George M. Gould's *Biographic Clinics* with the works of the literary body snatchers to which reference has been made. While their object is merely the satisfaction of curiosity, his book is an important contribution to science. His study of the mysterious sufferings which nearly wrecked the lives of Carlyle, Darwin, Browning, Huxley, and De Quincey has been made with a serious purpose. Convinced of the far-reaching constitutional effects of eyestrain, he wished to illustrate his teaching by a series of striking examples. He has certainly succeeded in drawing clinical pictures of the greatest historical interest, which immensely increase the admiration we feel for the great men who achieved so much under conditions of difficulty and disability that would have crushed ordinary men. We frankly say that we do not think he has established his case by scientific proof; but this failure can scarcely be laid to his charge, for there is too slight a basis of fact on which to rest a solid conclusion. The evidence largely consists of the illustrious patients' own testimony, which, moreover, is given in casual remarks without any particular sense of responsibility. It must be borne in mind that Carlyle and De Quincey were markedly neurotic, and that Browning was a poet. Huxley, too, had a highly-cultivated gift of expression. Descriptions of their own sensations and sufferings made by such men in corespondence or private intercourse cannot be accepted without a considerable discount for unconscious or half-conscious exaggeration. We have heard that a famous orator who went over to the majority some years ago occasionally misled his medical attendants by the lurid colors in which he painted agonies which, as a matter of prosaic fact, there was good reason to believe he had not to endure. We are quite willing to admit that writers who must of necessity also be great readers, and a considerable part of whose work is the correction of proofs, are very likely to overuse and thus damage their eyes. But this is not what Dr. Gould means by eyestrain, which he holds to be due to astigmatism. It may further be granted, for the sake of argument, that astigmatism is responsible for the manifold nervous and gastric, hepatic, and other derangements which he attributes to it —that, in his own words, 'the whole system must often become the vicarious sufferer for the sins of the eye.' Even if we admit that 'at least 80 per cent. or 90 per cent. of headaches and a very large proportion of digestional or nutritional diseases are dependent upon eyestrain,' and that there are in the civilized world 'at least 10,000,000 to 15,000,000' victims of that infirmity, it does not follow that the individual men of genius whose biographical records Dr. Gould has studied were the subjects of astigmatism or eyestrain. This particular fact, we repeat, he does not seem to us to have proved, and, in the absence of definite clinical proof, his explanation of the sufferings of Carlyle, Darwin, and the others, ingenious and plausible as it undoubtedly is, is merely 'bookish theorick.' We confess we have but little faith in master keys which unlock all the secret chambers of pathology. Some years ago the nose was declared by some to be the cause of nearly all the ills which afflict mankind. Now the eye is put forward as a rival: with a little ingenuity we have no doubt that a good case could be made out against the ear. We can easily imagine Hogarth's 'Enraged Musician' the victim of a devastating storm of reflex disturbances. If Dr. Gould's theory be true, nine-tenths of the illness not only of geniuses but of common folk would be cured as by a magician's wand by properly fitting glasses. The world's eyes are out of joint, he says in effect, and spectacles are the only wear. Only they must be made in America. To sum up: While fully recognizing the importance of Dr. Weir Mitchell's discovery that eyestrain is often the unsuspected cause of headache and other disorders, and the practical value of the labors of Dr. Gould and his fellow-workers in developing that discovery, we think that the case has been overstated to such an extent as to make its acceptance by reasonable men very difficult, if not impossible. Dr. Gould thinks statistically in millions as Cecil Rhodes, according to his admirer, Mr. Stead, thought in continents. Largeness of view is an excellent thing in medicine as in other things, when it does not lead to neglect of detail. Medical science, however, is built not on theories but on facts."

**Obituary.**—Dr. W. S. Playfair, the noted specialist and authority on obstetric medicine, died at St. Andrew's, Scotland, August 13. Dr. Playfair was born in 1836. He was a son of the late George Playfair, Inspector-General of Hospitals in Bengal. His education was obtained at St. Andrew's, and the young physician then became an assistant surgeon in the Bengal army in 1857. After teaching surgery for the year 1859-60 in the Medical College of Calcutta, he returned to London and practised there till his death. He was professor of obstetric medicine in Kings College, consulting physician for the diseases of women and children at the Kings College Hospital, and physician accoucheur to the Duchesses of Edinburgh and Connaught. He was a member of the Athenæum Club. Among his publications were 'The Systematic Treatment of Nerve Prostration and Hysteria'; a 'Handbook of Obstetric Operations,' and 'A System of Gynæcology,' which he jointly edited with Prof. Clifford Allbutt of Cambridge.

## CORRESPONDENCE.

### OUR LONDON LETTER.

(From Our Special Correspondent.)

London, July 25, 1903.

PHYSICAL DEGENERATION OF THE BRITISH RACE—WOMEN DOCTORS IN ENGLAND—HIGH FREQUENCY CURRENTS IN CANCER—THERAPEUTIC APPLICATIONS OF RADIUM.

We are at present in the throes of one of our periodical spasms of alarm about ourselves. At one time we are told that our trade is leaving us and that Germans are driving us out of the commercial field; another time we are being elbowed out of China by Russia; then our population is becoming stationary; now we are degenerating in physique. That there is some truth in the last notion is shown by a Memorandum that has just been issued by Sir William Taylor, Director General of the Army Medical Service. In that document it is pointed out that although statistics certify to a progressive improvement of the national health, and although athletic records are constantly being broken in regard to all sorts of feats of strength, agility and endurance, it is nevertheless true that a very large proportion of the men who offer themselves for enlistment in the Army are found to be physically unfit for military service. It was recently estimated by General Sir Frederick Maurice that out of every five men who offer themselves for enlistment there are at the end of two years' service only two remaining in the Army. Some are rejected by the recruiting officer; some by the examining medical officer, while others though enlisted are discharged after three months' trial as unlikely to develop into effective soldiers. That is to say, at the end of two years not more than 40 per cent. of the men who wished to become soldiers are actually serving; or, in other words, 60 per cent. of the men who offer themselves for enlistment are physically unfit to serve. This statement suggests the reflection, If these men are unfit for military service, what are they good for? Sir Lauder Brunton, a member of a Committee which has recently been investigating the physique of the rising generation of Scotland asks the same question with regard to the civil population: "Poor in physique as they all are, and poor in mental capacity and power of application as many of them must be, what becomes of them? Many of them probably marry girls as weak as themselves and have children, some of whom go to swell the lists of infant mortality; some to join the criminal classes, while others grow up more weak and incompetent than their parents." The Director General says that, whether the physical deterioration is partly the consequence of unskilled labor flocking from country districts into towns and there failing to find the means of properly rearing a family, or whether it be due to causes that can be remedied, such as too early marriages and the ignorance of the elements of hygiene on the part of mothers, the result is that among the male adolescents of all below the artisan class, a vast number are of a very low standard of health and physique. Every year there is published in the Report of the Army Medical Department a table in which the recruits examined are classified according to their previous occupations. Analysis of a series of these tables shows that the bulk of British soldiers are drawn from the class of unskilled laborers, that is, from the stratum of the population living in poverty. The recruiting statistics for a period of ten years (1893-1902) shows that the number of men medically examined for enlistment was 679,703 of whom 234,914 were rejected as unfit, giving a rejection ratio of 34.6 per cent.; of the men passed as fit 5,849 broke down within three months after enlistment being at the rate of .9 for this class, while 14,259 or 2.1 per cent. more were discharged as invalids under two years' service. Adding together the rates of rejection for the three classes, it will be found that 37.6 per cent. of all the men examined during the decennial period in question proved to be unfit for military service. It must, however, be borne in mind that these figures do not represent anything like the total number of rejections. A large number of men are rejected by the recruiting officers; these are not medically examined and do not appear in any returns. The Director General evidently thinks that Sir Frederick Maurice's estimate of a total proportion of 60 per cent. of rejection is not far from the truth. Examination of the statistics relating to the causes of rejection of men seeking enlistment by medical officers shows clearly that the majority are rejected on account of causes indicating poor physical development, namely, deficient chest measurement, deficient height and deficient weight. The causes of the decay in the British physique are only too obvious to those who know the conditions under which unskilled laborers, whether in country or in town, have to live in "Merrie England." The problem is an old one: "How is the multitude to be fed?" And further, how is it to be housed in a manner that shall satisfy the demands of common decency and the most rudimentary hygiene? The Director General seems to think that the causes of our physical degeneration have yet to be discovered, for he suggests that an inquiry on the subject should be made by a Commission "As to the composition of which the advice of the College of Physicians and Surgeons might be asked." The suggestion shows a singular confidence in the wisdom of two bodies whose advice in regard to public matters has always been marked by deplorable inaptitude. It was the College of Physicians which in 1867, in the face of the evidence contained in its own report, informed the Government of the day that leprosy was not contagious, a statement which led to the relaxation of measures of precaution throughout the colonies where the disease is endemic. The fitness of the Colleges for dealing with questions requiring even the smallest degree of breadth of view and practical statesmanship is sufficiently shown by the fact that at the present moment they are giving all their energies to an endeavor to defeat the efforts of the General Medical Council to make the five years' curriculum a reality and not a sham. A Commission has already investigated the question of the physical degeneration of Scotsmen, and nothing practical has so far come of its labors. Those of a Commission such as is suggested by the Director-General will doubtless have a similar result,

for, as Lord Salisbury said with cynical candor, no one—and least of all the Government—pays any attention to the recommendations of a Royal Commission.

A niece of Mr. Joseph Chamberlain was recently appointed resident physician at the Royal Free Hospital in this city with which the School of Medicine for Women is in organic communication. This year the school has 230 students, a fact which would seem to show that there is an increasing demand for the services of female doctors. There are now some 115 fully-qualified women practising medicine in London. According to a daily paper "in Wimpole Street there are seven, all, it is understood, with lucrative and increasing practices. Harley Street has four lady doctors," The streets named are two of those where doctors most do congregate, but it by no means follows that the fact of having a brass plate on the door of one of the mansions of these gloomy but fashionable thoroughfares implies a lucrative practice. At the New Hospital for Women, there are two lady doctors on the consulting staff, and thirty-three acting and visiting physicians and surgeons. There are female medical officers at the Canning Town Hospital, Blackfriars Provident Dispensary, Church Army Dispensary, Homer Street, and at the Institution for Diseases of the Eye at Fulham. At the Clapham Hospital, Jeffreys Street, the medical staff includes two ladies. The honorary acting physician at the Midland Hospital, Birmingham, is a lady, and there are visiting or resident lady physicians and surgeons at hospitals in Manchester, Edinburgh, Glasgow, Dundee, Hull, Bristol, Birkenhead and Oxford. Notwithstanding all this it is extremely doubtful whether the movement for admitting women to the medical profession has so far been justified by success in this country. There are several women who earn a respectable living and one or two who have what would be called in the case of a male consultant, a third or fourth rate practice. A few have cooperated in scientific investigation, but not one has independently made a discovery of any note or an original observation of any particular value. There are two or three ladies who operate with fair skill, but not one who has achieved anything like brilliant success in that line. The case is fairly put by a well-informed writer in a recent number of the *Cornhill Magazine*: "It is now many years since the obstacles which debarred women from entering the profession were removed, and the prejudice which the idea of a woman practising medicine aroused a generation ago is now well-nigh extinct. In London, in the North of England, in Scotland, in Ireland, and in Wales alike, the door is open and women have no difficulty in finding the best of professional education. In the University of London, as well as in Manchester and in the universities of Scotland and Ireland, a surprising number graduate each year and acquit themselves as creditably as their masculine *confrères*. Some reserve, however, must be observed in recommending the medical profession as a career for women. India has undoubted need of women doctors and absorbs a large proportion of each batch of graduates; but, so far, there are few signs that any large public demand has been created for them in their own country."

Quacks, like the poor, we have always with us, but at the present time the cancer quack is more than usually prominent in the newspapers here. The most pushful among them are, I am sorry to say, legally qualified members of the medical profession. These men somehow manage to get the most shameless puffs of their methods and results inserted in leading papers. When charged with unprofessional conduct, the injudicious friend is put forward as the offender, and the official censors of the morals of the profession are helpless. The "high frequency current" is now the most popular of quack cures for cancer, and as nobody knows much about its effects it is not easy to expose the hollowness of their pretensions.

Attempts to warn the public are practically useless because they are put down to the jealousy of the doctors who are credited with the desire to suppress all knowledge but that which is the property of their own craft or "mystery." Not long ago an enthusiastic lady sent the following letter broadcast throughout the land. As far as I am aware it has not yet seen the light but I think it deserves publicity. I suppress the name of the writer and of the doctor whom she advertises:

"You ask me to tell you more about that new treatment for Cancer of which I spoke in our mutual friend's drawing-room, but as nearly everyone who was present has made the same request, I am having an answer printed to send round to friends. It is called the 'High-frequency treatment by electricity; not the '"X" Rays,' not the 'Finsen Light' so successful in the cure of Lupus—but a much newer thing only discovered during the last few months. I hasten to add at once that it gives no pain, no discomfort to the patient—rather indeed, a pleasant feeling of exhilaration. By the exceeding force and strength of its oscillations (120,000 per second, equal to 1,000 volts) it kills the germs of the disease, causing the fibers and feelers running to the cells to, so to speak, loose their hold or grip, thus preventing them from sucking up fresh nourishment and generating new life. Consequently, they gradually begin to perish, to wither and to shrivel away. No medicine ever yet invented can do this, no knife yet made either. You ask me why? Because, though a knife may cut away the body of the disease so that it may heal *for a time*, it cannot possibly reach and cut out all these fibers and feelers with their tentacles—or whatsoever they may be—which, still embedded in their cells, suck up nourishment and generate new life and form a new body. The knife may give these fibers a sort of little shock *for a time* which allows the surface of the wound to heal *for a time*, but the germs soon begin to get active again and to work new mischief. The tremendous power of this new 'high-frequency' treatment kills these germs at the very root of their cells. I wish I could put it more scientifically and technically. It is being practised successfully at some hospitals, but very few private doctors have yet been able to go in for it, as the complete apparatus is not only enormously expensive, but so very few medical men are deep students of Electricity, with all its vast possibilities. However, one of the first and foremost of these 'few' is, as I told you, ——. He goes, and has gone from the beginning, heart and soul into it, from the time the 'X' Rays were first started, has kept pace step by step with each new discovery, and has the whole apparatus in full working order in his own house. I may just mention too, that one of the most useful points about the treatment is that it never fails to alleviate and soon remove the agonizing pain; while in cases of disorders of the nerves and depression of spirits it is wonderfully efficacious. I do think it is everyone's duty to spread such valuable information far and wide. Do not you?"

A copy of this letter was sent to the King who with characteristic good sense merely acknowledged its receipt and caused the writer to be informed that he had sent it on to the College of Physicians, the President of which, Sir William Church, is also the President of the Cancer Research Fund. About the same time an article appeared in Mr. Astor's paper, the Pall Mall Gazette, in which the marvellous effects of the "new" treatment—described as "a triumph of electricity"—in the hands of the same man were vaunted in the most flamboyant style. This moved Sir William Church to point out that the doctor thus presented to the world

as a scientific pioneer and a medical savior of society had not the slightest claim to be considered the inventor of electric currents of high-frequency, or as the originator of the application of such currents for the relief of pain or for the treatment of disease; high-frequency currents having been in use for these purposes for several years. He challenged the bepuffed practitioner to submit any evidence he might have collected as to the value of high-frequency currents in the treatment of cancer to the Cancer Research Association. It is needless to add that the challenge was not accepted. But not long afterwards one of our papers—The Daily Mail—which models itself on your yellow journals thrilled the country with the announcement that the Royal Commission on Cancer was about to present a report in which high-frequency currents would be recommended as the most effective treatment. This statement, obviously inspired by some of the charlatans who are "running" the treatment, was at once shown to be a pure fabrication and a very clumsily constructed one, inasmuch as no Royal Commission has ever been appointed to investigate cancer and consequently the report and its recommendations were alike imaginary. There are some earnest and honest men who are making a trial of the high-frequency currents, but it is difficult to get information about their work. I am informed that one of our foremost dermatologists has obtained remarkable results by the method, but as he does not yet know how the treatment acts or in what cases it is likely to be efficient, he does not care to publish anything on the subject at present. I have also heard of an apparently complete cure of uterine cancer in a case under the charge of a well-known gynecologist whose reputation for perfect integrity no breath of slander has ever dimmed. On the whole, however, the experience of those who have worked in a really scientific spirit with the high-frequency currents in this country may be summed up in the words of our leading authority in that line, Dr. John Macintyre, of Glasgow, who said not long ago that although the treatment had good constitutional effects and occasionally produced some amelioration of local conditions, he had never seen any case of cure of cancer by this method.

The same careful observer has lately been experimenting with radium. His conclusion is that it cannot be doubted that the salts of radium have an action on diseased tissues, but it cannot yet be said whether they will take the place of some of the other forces, such as X-rays, etc., at present employed in the treatment of lupus, rodent ulcer, and superficial epitheliomata. All that can be said is that something emanates from the compounds of radium which has a very exciting effect and, if pushed far enough, even a destructive power on healthy tissues. The method which he employs is to have the radium enclosed in a small cell with a mica front ½ inch in diameter. This is surrounded by a small piece of indiarubber tube. He has a number of cones made with an opening at the apex into which the indiarubber fitted. They vary in size and depth, but those chosen are usually about ½ inch in depth. The radium is applied to the parts for a period of twenty to forty minutes daily or longer, and the effects on the patients are watched with comparatively little risk. In a case of lupus of the back of the hand the application of radium caused disappearance of the lesion in three weeks; and in one of lupus of the nostrils and nose healing took place in four weeks. Recurrence, however, was observed within two months. In a case of rodent ulcer still under treatment, improvement has been noted. Mackenzie Davidson of the Charing Cross Hospital has confided to a reporter of the Daily Express that he has had strikingly successful results with radium in cases of "cancer," that is to say rodent ulcer. As to deep tumors he said he could not speak, but he let it be understood that he is hopeful. Although he allowed himself to be interviewed by the representative of a newspaper not particularly trustworthy in matters of science Mackenzie Davidson is a thoroughly sound man. Otherwise I should not refer to his work. It is suggested by Mr. Soddy, assistant to Sir William Ramsay, one of the discoverers of argon, that the "radio-active emanations" of radium and thorium may be applied by inhalation to the lungs of sufferers from consumption. We are, it seems to me, like Cortes and his men when, standing upon a peak in Darien, they first beheld the Pacific.

## EVIAN-LES-BAINS.

French Savoy, August 6.

*To the Editor of the* Medical News:

Dear Sir: The season at charming Evian-les-Bains is now in full swing. It is surprising that a spa which unites so many advantages, of location, climate, excellent mineral waters and artificial attractions, is so little known in America. According to the writer's observation the ubiquitous Yankee tourist simply takes a little run over to Evian from Geneva or Lausanne, strolls along the quay Baron de Blonay, and is off on the next steamer. A few American dyspeptics and sufferers from renal and hepatic disorders are found among the large number of valetudinarians, but not near so large a proportion as one sees at other European watering places affording less promise of benefit.

Evian-les-Bains is located on the east shore of the Lake of Geneva, on the Paris, Lyon and Mediterranean system of railways, about 625 kilometers from the French capital. It may be reached in two hours by rail, and in a slightly longer time by steamer from Geneva. The season extends from May 15 to October 1, and the prescribed time of treatment is from twenty-five to thirty days, according to the direction of the physician. The strict surveillance exercised over the health-seeker at the Geneva spas is somewhat relaxed here, the pleasure-loving Latins evidently not being able to tolerate so rigid a régime. It is not to be doubted, however, that excellent results are obtained at Evian. The daily routine is about as follows: Rising at 6 o'clock (the sun in July and August is 1½ to 2 hours high at that time) drinking one or two glasses from the Lower Cachat, taking the bath or douche during morning or afternoon hours according to doctor's orders. A promenade or enjoying the music at the Cachat. At 8 o'clock breakfast; at 10.30 coffee and dominoes at Casino. Concert from 3 to 5 P.M., followed by promenade. Table d'hote at 6, and at 8 grand concert at the Casino or the play at the theater. One may vary this routine by a sail on the lake. A little walk to the rising ground just back of the lakefront where a magnificent panorama of Mont Blanc, the Dent du Midi and other Alpine summits may be had, or in driving, fishing and various other diversions. At the magnificent Institut Hydrotherapique, recently completed, besides the various forms of hot and cold baths, sprays and douches one finds an excellent gymnasium and a very elaborate electrotherapeutic and mechanico-therapeutic plant. The hotels are numerous and very comfortable, some indeed quite luxurious. The best accommodations may be had at prices ranging from 8 to 15 francs per day for board and room. An almost ridiculously low figure to the American traveler accustomed to Saratoga and other high-class resorts in the United States. The Lower Cachat, which has been in constant use since 1789, is the principal mineral water fountain. The latest reliable analysis made in 1892, by Willm, of Lille, is as follows, estimated in grams per liter:

| | |
|---|---|
| Calcium carbonate | 0.1960 |
| Magnesium carbonate | 0.0816 |
| Sodium carbonate | 0.0056 |
| Calcium and iron phosphate | 0.0008 |
| Sodium sulphate | 0.0079 |
| Potassium sulphate | 0.0052 |
| Sodium chloride | 0.0030 |
| Sodium nitrate | 0.0029 |
| Silica | 0.0142 |
| Lithium iodide | Feeble traces. |
| Carbonic acid as bicarbonates | 0.2627 |
| Carbonic acid, free | 0.0105 |
| Total fixed matter per liter | 0.3172 |

From 5 to 15 glasses are taken daily in accordance with the instructions of one of the medical attendants at Evian, of whom there are a dozen or more. The water is very pure and limpid and sparkling.

The analysis shows a very excellent alkaline-carbonated water with ferruginous properties. We have many such in America. If better results are obtained at Evian than at most American spas, it is not due to the superiority of the water, but to the fact that long years of observation and experience have taught the medical men of France that the use of mineral waters is only supplementary to temperate habits, careful diet, etc.

The time is not far distant, the writer trusts and believes, when our own beautiful spas, uniting all the natural attractions which this old earth can afford, will find their proper sphere in medical practice and popular esteem. J. K. C.

## SOCIETY PROCEEDINGS.

### BRITISH MEDICAL ASSOCIATION.

*Seventy-first Annual Meeting, Held in Swansea, July 28, 29, 30 and 31, 1903.*

(Continued from Page 336.)

**Discussion on the Vaccination Acts and the Prevention of Smallpox.**—Dr. McVail said: "Coming closely to the subject of discussion, the question of vaccinal legislation presents so many aspects as to make it almost impossible to do more than indicate the principal points that call for consideration. But perusal of the weekly reports in the *British Medical Journal* of smallpox in the provinces during the recent widespread prevalence of the disease suggests the importance of obtaining under Act of Parliament special powers for meeting special difficulties. When the country is threatened by cholera or plague the Local Government Board is in the habit of using its powers under the Public Health Act to bring into operation various provisions which are at other times in abeyance. Similarly, when smallpox threatens, the Board should be in a position to issue epidemic regulations either to the whole country or to a defined area. Such regulations should be perfectly definite in scope and purpose, and should at no time be open to the charge of being framed ultra vires. One matter of special importance with which the regulations ought to deal is the prevention of the spread of smallpox by tramps or vagrants. The part played by such people in conveying the disease has long been known, but has lately been much emphasized. Their migratory habits make it very difficult to procure anything like universality of vaccination of their children, or revaccination of their adolescents and adults. At the same time the opportunities which they have of carrying the disease from village to village and from town to town make them a most serious danger to the nation. The question is what exactly should be the measures enforcible on them. If we assume that next year will see the passing of a Revaccination Act subject to an exemption clause, should tramps who have been in contact with smallpox and require vaccination be excluded from the operation of the clause? In other words, Should compulsory vaccination in their case be absolute? To such a question one naturally replies with an emphatic affirmative, but on consideration I doubt if it would always be found a practicable measure. Even if contacts have chanced to stay on in a lodging-house until the case of smallpox to whose infection they have been exposed has been discovered, the time required to set in motion actual compulsory powers of vaccination, say, by order of a magistrate, might give the variolous disease too long a start to permit of its being overtaken. But quite possibly after exposure to smallpox a whole lodging-houseful of tramps may have distributed themselves all over the country before the existence of the disease had been recognized. In fact, if Parliament is to take any action of this sort, such powers should apply, not merely to tramp contacts, but to all tramps within the scheduled area of the epidemic regulations. Wherever found their vaccinal condition should be ascertained and recorded, and if necessary they should be vaccinated. It can readily be conceived that during smallpox prevalence local authorities may be more anxious to get rid of tramps than to obtain them for vaccination. If there is a risk in their thus being posted on from union to union it might be got over by charging the cost of their vaccination on a wider basis than that of the union—say that of the county, or of the whole area under epidemic regulations—an area which might sometimes be the whole country.

"But quite possibly the legislature may not, even under restrictions of time and place, exclude vagrants from the operation of any generally applicable exemption clause. In that, as in the entire domain of obligatory vaccination, Parliament must, of course, do just as it pleases. If it will not actually enforce the vaccination of vagrants, is there any useful alternative? In recent years tramps under vaccination in lodging-houses have sometimes received from local sanitary authorities a few days' board and lodging. The right to offer this without any question of subsequent surcharge by a public auditor should be definitely conferred by statute. With regard not to tramps in general, but only to tramp contacts, the further suggestion arises whether, in the event of their refusal to accept vaccination, or of the time being obviously past to make smallpox prevention probable, there might be a regulation for their compulsory detention until the incubation period of the disease had gone by. That would sometimes be a very useful measure, and possibly Parliament might sanction such a degree of interference with the liberty of the subject. The usual steps to prevent spread of infection immediately by means of clothing or person would, of course, be taken in every case.

"Under epidemic regulations there ought further to be the amplest powers, not merely for inspection of every place resorted to by vagrants and navvies, whether or not such place be registered as a common lodging-house, but also for the examination of all persons found in such premises, even in the absence of any special reason to suppose them suffering from smallpox. In the Public Health (Scotland) Act of 1897, Section 45 enacts that the medical officer of health may in the daytime enter and inspect any house where he has reason to believe that any infectious disease exists or has recently existed, and may examine any person found in such house. This power to examine persons in addition to premises should, under the regulations, be given independently of actual suspicion of the existence of smallpox in the house. Needless to say, such

a right of examination of apparently healthy persons would constitute a considerable interference with personal liberty. Whether Parliament would grant it I have no idea. Our point is that it would be useful for the detection of smallpox and for the ascertainment of the vaccinal condition; but if the legislature would prefer to risk smallpox rather than confer the power, then it is not we who would have cause to grumble. Once more our advice would be justified by the results either of its acceptance or of its rejection.

"Concerning the relation of the private medical practitioner to official vaccination there are differences of view. I think myself that if a fee were paid for every certificate of vaccination complying with a standard of area and number of marks to be prescribed by the Local Government Board, the effect would be to promote the practice of efficient vaccination without the formal appointment as public vaccinator of every medical man who might choose to apply. If certificates were to be paid for, false certification should be a heavily punishable offence. At present public vaccinators are under serious hardship in being merely contractors dismissible at four weeks' notice, and without any proper official status. This should be remedied in any new legislation. If systematic vaccination and revaccination are to be obligatory, then the evolution of the public vaccinator ought to be toward whole-time service, and, at reasonable salaries, that system ought to be economical as well as efficient. It would not come into force all at once, but as appointments become vacant areas could be combined under one officer."

**The Midwives Act of 1902.**—J. Ward Cousins said: "Up to the first day of April, 1903, any uneducated woman, without any training or experience, could style herself a midwife, and practise as one in any part of England and Wales. This statement is correct; and it appears hard to understand that our country should have so long been behind other European nations in seeking legislation for protecting the lives of women of the humbler class who are unable to obtain skilled help in the hour of danger. The Midwives Act of 1902, there is every reason to hope, will steadily wipe out the ignorance and incapacity of the past. It provides a Central Midwives Board to regulate the training of midwives, the issue of certificates after examination, and the annual publication of a Midwives Roll. Moreover, the Board is empowered to regulate and restrain within proper limits the practice of midwives, and the carrying out of all the provisions of the Act, with the approval of the Privy Council. After April 1, 1905, no woman will be able to style herself a midwife unless certified under the Act. After April 1, 1910, no woman will be allowed to practise for gain as a midwife unless she is certified as the Act provides. Up to March, 1905, women holding certain certificates mentioned in the Act, or other certificates approved by the Midwives Board, may claim to be certified. Women also who can satisfy the Central Board that they have been in actual practice as midwives for at least one year prior to July 31, 1902, and that they bear a good character, may claim to be certified under the Act.

"Now, the largest number will be admitted as midwives, and will be placed on the first roll, belong to the third class, and many of them will have been very imperfectly trained. Now, let us hope that the local supervising authorities throughout the country will be able to find some means of helping these women to obtain an increase both of knowledge and efficiency.

**Local Supervising Authorities.**—"The Midwives Act is to be carried out by the important process of decentralization. Every council of a county or county borough throughout England and Wales is the local supervising authority over midwives, but these bodies can delegate their duties to committees or to the district councils. The provision for carrying out the Act by the help of local bodies is a very helpful and practical method. Local bodies are well able to do the work and look after their own interests, and it is my opinion that the success of the Act will greatly depend upon the work done by the local supervising authorities.

"The local authorities may delegate their powers to a committee consisting wholly or partly of members of the council. The Act wisely permits also the appointment of women members on the committee, selected by the council, and as the Act principally involves the interests of women, it appears very desirable that the authority should secure the services of two women at least who are recognized workers and conversant with the needs of the locality.

"In Sweden the midwife has to be examined every year by the officer of health of the district as to the state of her knowledge in the presence of witnesses, and should her knowledge on any material subject be found deficient she can be suspended for a period from practice.

**Duties and Restrictions.**—"The midwife by the Act is permitted to attend normal labor only, and she is compelled to send for a qualified registered practitioner in every emergency. Her ability to recognize danger and abnormality in either mother or child will be an important test of her training and efficiency.

"The midwives in Switzerland are required to make a solemn affirmation on receiving their certificate. They promise on oath to practise their profession with reverence, patience, and earnest endeavor, and on every occasion to send for a physician in all abnormalities and also to abstain from intermeddling with his duties. If any midwife outstrips her powers in practice she can be fined from 10 to 1,000 francs.

**Midwives and the Prescribing of Drugs.**—"I shall now refer to a subject on which I find there is great difference of opinion. Some consider it sufficient for a midwife just to enter in a book every occasion on which she is under the necessity of administering any drug, whether scheduled as a poison or not, the dose, and the time and cause of its administration. Others are of opinion that the safety of women will be endangered if active remedies are placed in the hands of any one but registered practitioners. They consider that any ordinary remedy that the patients themselves would take may be suggested by the midwife; that in a great emergency, whenever an active drug is administered, the case must be considered abnormal and a practitioner must be consulted. Can, then, the administration of morphine, opium, or other dangerous remedies be placed at the discretion of thousands of unqualified persons who are only certified for attendance upon normal labor, without involving the safety of the public?

"In Sweden midwives are allowed to give some ordinary remedies, but they are bound by law not to order any active medicine for either the mother or the child without calling in a medical man.

**Notification.**—"The duty of notifying an infectious fever must be undertaken by the registered practitioner who is called in by the midwife to attend the case. Medical men are required to notify puerperal fever and other infectious disorders. The midwife does not diagnose the disease, but sends for the doctor on the occurrence of urgent symptoms. The record of the midwife will show the number of cases of fever which have occurred in her practice, and the name of the doctor who assisted her. Information of all cases of

fever ought to be forwarded at once to the local supervising authority, and also to the county medical officer of health.

"After any attendance upon a patient suffering from puerperal or any other illness supposed to be infectious, the midwife must disinfect herself, her appliances, and have her clothing thoroughly disinfected before going to another case. The local supervising authority may suspend a midwife from practice if suspension appears necessary to prevent the spread of disease. In Sweden a midwife must abstain from practice for a week after attending puerperal fever, and live as much as possible in the open air.

**Stillbirths.**—"The number of cases of stillbirth in any area is at present unknown, and we can not attempt to ride over existing legislation. The midwife has no power to grant any medical certificate or any certificate of stillbirth or death. Her record, however, will show the number of cases of stillbirth that she has attended, and this number will be considered by the local supervising authority. In this way the total number of stillbirths attended by certified midwives within any area can be readily ascertained. Beyond this voluntary information nothing can be known, and for the present we must wait for the amendment of the law as to death certification and registration. Stillborn children are too easily disposed of, and no doubt many evils and irregular practices are hidden which ought to be investigated. Let us hope that the successful working of the Midwives Act and the records of the local supervising authorities may turn out to be the successful insertion of the thin end of the wedge of progress.

**Improved Household Sanitation.**—"The educated midwives will help their patients to put in order their houses and carry out sanitary precautions for their own protection. They will teach personal cleanliness and the value of cleanliness at home, and, as far as possible, they will surround their patients with sanitary precautions. I believe that the work of midwives in promoting reform in the houses of the poor will have a wide and wholesome influence. They will be brought face to face with the question how best to deal with overcrowded and insanitary areas, and their efforts will tend to create a broader interest in the subject of rehousing the poorer classes under new conditions which will benefit their health and arrest the spread of disease. Interest has been recently manifested by the activity of many members of Parliament, by the introduction of projects for remedial legislation, and by the work of many voluntary associations, and I think it is not too much to hope that indirectly the silent work of educated midwives will prove a wholesome stimulus to the higher classes of society and arouse their sympathy in the great work of improving the dwelling houses of the laboring classes of our country.

"England and Wales have long been lagging behind France, Russia, Sweden, Germany, and Switzerland in the education of State control of midwives. The great importance of the reform in the practice of midwifery in our country has long been loudly accentuated by the consideration of the small number of trained and intelligent midwives at the present time compared with the host of unqualified and ignorant women who are unfortunately almost everywhere engaged by the humbler classes. It has been estimated by authorities that 60 or 70 per cent. of the births in Great Britain take place without the presence of a qualified practitioner, and that in many of the poorer districts as many as 70 or 90 per cent. of the births are attended by women. Surely these statements demand our earnest consideration, and I am bold enough to express a hope that more general interest will be developed in this great step in the right direction, especially when we consider that the dangers of childbirth are practically confined to the poorer class of our countrywomen, who, from lack of means, are unable to obtain skilled labor in the hour of need."

**Spread of Enteric Fever and Other Forms of Illness by Sewage-polluted Shellfish.**—Dr. Arthur Newsholme, of Brighton, said that in March, 1894, he reported to the Brighton Town Council a series of cases of enteric fever and diarrhea which appeared to be due to oysters obtained from polluted layings at Southwick, near Brighton. A copy of this report, with further details based on later experience, will be found in the forthcoming volume of evidence before the Royal Commission on Sewage Disposal.

The evidence on the strength of which enteric fever, attacks of diarrhea (resembling those caused by the Gaertner bacillus), and allied illnesses are ascribed to the ingestion of oysters and other mollusks requires consideration in connection with outbreaks of two kinds —(*a*) sporadic cases, (*b*) definite groups of cases. Of the latter the most remarkable are the outbreak among the students of the Wesleyan University, Connecticut, in which 25 per cent. of the students attending an oyster supper were subsequently attacked by enteric fever, and the simultaneous outbreaks following after mayoral banquets at Winchester and Southampton recently reported on by Dr. Bulstrode. In these two outbreaks, out of 266 total guests 21 (all of whom had eaten oysters), or about 8 per cent., suffered from enteric fever, while 118, or 44.3 per cent., of the total guests, all of whom except 3 had eaten oysters, suffered from minor forms of illness. In the two banquets 38 guests are stated not to have eaten oysters; none of these had enteric fever, hence the number of attacks among oyster eaters was 9.2 per cent. In Brighton the cases ascribed yearly to this cause (21 in 1894, 19 in 1895, 31 in 1896, 30 in 1897, 41 in 1898, 52 in 1899, 17 in 1900, 9 in 1901, and 21 in 1902) have in most instances occurred sporadically at irregular intervals and without any demonstrated relationship to other cases. In other words, on the assumption of causative relationship to the Southwick oysters which had been eaten by the patients, the infection must have been frequently present in a certain proportion of these oysters. In the paper already mentioned, he showed that this fitted in with the epidemiological facts of the case, no long interval elapsing between the occurrence of cases of enteric fever in the Southwick and Shoreham districts and in the inhabitants of Brighton who had eaten oysters or mussels contaminated by the Southwick or Shoreham sewage. It is obviously much more difficult to prove the relationship between cause and effect in connection with such sporadic cases than when definitely associated cases occur. The chief evidence on the strength of which he arrived at the conclusion that this fairly steady stream of sporadic cases was caused by sewage-polluted shellfish may be classed under four heads: (1) Clinical evidence; (2) exclusion of other known causes; (3) topographical evidence; (4) bacteriological and chemical evidence. These are placed in the order of importance. The three first are, he thinks, immensely more important and more trustworthy than the fourth, both on the negative and the positive side, though no line of evidence should be neglected.

**Clinical Evidence.**—The clinical evidence is usually as follows: About ten to sixteen days after eating oysters or mussels the patient fails with enteric fever. Very often the definite attack of fever has been preceded by a violent attack of diarrhea and vomiting occurring about twelve to twenty-four hours after the ingestion of the shellfish. Either (1) the person who

has partaken of the shellfish is the only one affected, or (2) other members of the family who have partaken of shellfish at the same time escape or suffer only from minor disorder. Numerous instances of both these are given in my annual reports. In the latter cases it is occasionally observed that the patient noticed something "queer" about his share of the oysters. Further, it is to be remembered that only a certain proportion of persons are susceptible to infection, that it is not reasonable to assume that every mollusk from a sewage-polluted source contains the typhoid bacillus, and that, even when an outbreak of enteric fever is caused by contaminated milk or water, only a small percentage of the persons drinking these are attacked.

The clinical evidence is supported by the ability to exclude other known causes. Cases of enteric fever due to contaminated water or milk nearly always occur in groups, while those due to oysters and other mollusks are, apart from certain exceptional outbreaks, generally sporadic. In a minority of the cases the possibility of the attack of enteric fever being caused by defective house drains had to be considered. On this point it was noteworthy that the attack generally occurred in the head of the household, who was least at home, his wife and children escaping. As more exact inquiries are made, it will now be generally agreed that defects of house drainage as a cause of enteric fever can be relegated more and more into obscurity. Given, on the one hand, bad drains, and on the other hand the fact that the only person suffering in a given house from enteric fever has partaken of oysters known to have been subject to pollution by sewage, we are bound to decide that in all probability the latter are responsible for the attack of enteric fever.

The topographical evidence is as follows. The oysters or other mollusks are traced to their original layings. In these layings, or more often in the market ponds in which they are finally placed before being sent to market, the oysters are found to be subjected to more or less gross contamination by sewage. The gravity of this contamination depends upon the proximity of the sewage outfall to the layings or the ponds, on the set of the tides, and on the size of the population whose sewage discharges at this point. Obviously the risk of the typhoid bacillus being conveyed to the oysters is much greater if they are subject to contamination by the drainage of several thousand persons than if only a small hamlet is concerned in the pollution. In his own experience, which has been concerned chiefly with oysters and mussels from Shoreham Harbor (Southwick, etc.) and with oysters from Emsworth, there has been no difficulty in stating that there has been sewage-contamination of the grossest character.

Bacteriological and chemical evidence has been placed last, as least important. It is not for him to assess the value attaching to the detection of the *Bacillus coli communis* in a given oyster. He is quite clear, however, that if this organism were not found he should brush the certificate to this effect aside as valueless in the face of clinical and topographical evidence that oysters from a given source were responsible for cases of enteric fever. If it were found its presence would be useful confirmatory evidence

**River and Seashore Pollution as it Affects Shellfish.**—Dr. T. C. Nash, Medical Officer of Health, Southend-on-Sea, said: "In my opinion it should be illegal to expose shellfish for sale unless they are from layings which are either entirely above suspicion, or at any rate are a very considerable distance from any obvious source of pollution, and in such a position as to be covered with seawater at all states of the tide, and unless a bacterial standard such as I have suggested elsewhere[1] is satisfied. I feel inclined to go even further, and say that, as with a public water supply, so also with all kinds of public food supplies, including shellfish—it ought to be an absolute condition that these should be uncontaminable by drainage. A proper control of shellfish will, I think, secure a notable reduction in the seasonal incidence of typhoid fever and a moderate reduction in that of diarrheal diseases generally.[2]

"There is bound to be some opposition in enforcing restrictions on the shellfish industry until the shellfish merchants recognize that it is in their own interests to take every possible care to obtain their shellfish from the purest possible layings. As a public health officer I consider it my duty to warn the public against eating shellfish from sewage-contaminated sources. In my own district the majority of the local shellfish merchants have realized the importance of taking every possible precaution. They now obtain their cockles from Whitstable from a spot well removed from any obvious pollution, instead of from the sewage-contaminated creek in a neighboring district as formerly. In addition they boil them for at least three minutes and a half in pure water. If all cockle vendors would take the same precautions, I venture to think that this variety of shellfish might be safely eaten, and that the cockle industry, if intelligently and carefully managed under proper sanitary supervision, may yet flourish and cease to be a serious danger to the public health.

"With respect to oysters, however, the conditions as to the cultivation, layings, and supervision must be most stringent and exacting, because this form of shellfish is generally eaten raw, and is, in my opinion, dangerous unless all the conditions are above any suspicion of sewage pollution.

"I have noticed that, generally speaking, the type of typhoid fever following the ingestion of par-boiled cockles is milder than that observed when raw shellfish are eaten. The inference is that the partial cooking of cockles has diminished the numbers or attenuated the virulence of the contained pathogenic bacteria of typhoid. On the other hand, Dr. Elliston of Ipswich has observed a severe type of typhoid fever following the ingestion of raw cockles collected from the Orwell. This would be in acordance with Dr. Klein's observation that typhoid bacilli actually multiply within the cockle even though the cockles may be put to clean for three days in clean seawater. The importance of these observations can not be overestimated, nor those of Professors Klein, Boyce, and Hewlett, that the oyster naturally does not contain the *Bacillus coli* or *Bacillus enteritidis sporogenes*, and that, therefore, the presence of these organisms is strong evidence of pollution of the shellfish by sewage or a sewage effluent.

"We must remember that different kinds of shellfish are eaten by different classes of people largely according to their means. This was happily put by Sir James Crichton-Browne, who spoke of 'the aristocratic oyster, the plebeian cockle, and the Hooligan mussel.'[3] We must also bear in mind that other forms of food besides water, milk, and shellfish occasionally carry the infective germ of typhoid. In my experience watercress is the next most likely agent, and this is not to be wondered at, considering that this pleasant vegetable is often obtained from streams which are liable to occasional pollution, if not constantly polluted. Other uncooked vegetables such as salads, lettuce, and radishes must also be borne in mind. Ice creams may occasionally be the vehicle. It is important to point out that whenever shellfish or uncooked vegetables are the vehicles of infection, the real source of infection is really, as usual, a polluted water, and therefore really only another form of water-borne typhoid.

"Uncooked vegetables are eaten in all parts of the

country, but it is a significant fact that typhoid fever is, as a rule, more prevalent in littoral coast towns (this is so at least in Essex), where shellfish are abundant; and in large centers of population inland which import considerable quantities of shellfish. Infected dust and fabrics, and flies,[4] no doubt all play some slight part in securing the admission of typhoid bacilli to articles of food, or directly to the mouth; but in my opinion these sources of infection are comparatively rare in this country. But infected fabrics and infected flies certainly account for a considerable proportion of secondary cases where the primary cases have followed the use of infected water, milk, or shellfish.

"Schemes for the purification of sewage may prove disastrous as regards the pollution of shellfish. The creek to which I have alluded more than once is a case in point. Though this creek has for years past been subjected to some pollution by the discharge of crude sewage, it latterly has received the sewage of the whole town, which numbers about 4,000 residents, besides a considerable number of visitors in the summer. The sewage is treated bacterially in contact beds, and the effluent is discharged into the creek a few hundred yards above the cockle layings. Though a considerable degree of chemical purification may be thus achieved we know that bacterially the effluent is practically as impure as the crude sewage, and that we can not expect contact beds to keep back typhoid bacilli. Hence this method of sewage treatment has rendered this creek even more dangerous than formerly, for whereas formerly, it was necessary for one of only a very few houses to harbor a case of typhoid fever in order for the specific germ to enter the waters of the creek, nowadays it is only necessary for a case of typhoid fever to occur anywhere in the town, even a mile away, to run the almost certain risk of pollution by the specific microbe. Hence these cockle layings are obviously much more dangerous since the bacterial beds installation than formerly. This is an important point to bear in mind when advising a sanitary authority as to the treatment of sewage for a town which has a shellfish industry."

## BOOK REVIEWS.

The American Year-Book of Medicine and Surgery, 1903. Under the General Editorial Charge of Geo. M. Gould, M.D. W. B. Saunders & Co., Philadelphia, New York, London.

If we attempt to compare any one, or all, of the numerous year-books with this volume, a novice would at once comment on the impossibility of the task. In typography, in bookbinding, in the detail of its general management, in the importatnce given to the most critical points of surgical progress—in short in every respect, this year-book is fully equal to its predecessors. No student or practitioner who wishes to keep abreast of the times can possibly dispense with it.

A full and interesting account is given of the classic case of President McKinley. Particular attention is shown the new methods of massive infiltration anesthesia as perfected by Matas, and that new and important department of surgery which deals with the mitigation of deformities by the subcutaneous introduction of paraffin has received most careful attention.

Of particular interest in the Section on Obstetrics is the detailed article touching on the xiphopagus twins Radica and Doodica. Gynecology received its full share of space and an unusual amount of illustrating is accorded it. Not unimportant are the full details of an improved angiotribe with an illustration of its application to hysterectomy. Orthopedic surgery receives apt attention, a simple and practical wrench for the correction of stubborn deformities being among the important devices shown. The eye, ear, throat and nose are given generous space and should be looked over by everybody interested in those departments of surgery. Last but not least, is a chapter on anatomy which relates the findings both microscopical and macroscopical of the last year.

The Protozoa and Disease. By J. Jackson Clarke, M.D., London. William Wood & Co., New York.

This small work of 177 pages is an excellent straightforward account of the many forms of protozoa that are known to infect man and the lower animals. The book is to be preferred to many similar works of the kind in that, instead of presenting a discrete, unorganized series of facts concerning this important branch of parasitology, it deals with the subject: (1) from the strictly zoological point of view and (2) from the standpoint of the systematic student. Thus, whereas one might consider at first sight a preponderance of zoological information in the work to the detriment of its pathological relationships, it must clearly be seen that if one is to get a thorough knowledge of this steadily widening branch of medicine it will be necessary to get at the fundamental anatomical features of this class of organisms. The work's conciseness as well as its logical arrangement commends it.

The Roentgen Rays in Medicine and Surgery as an Aid in Diagnosis and as a Therapeutic Agent. Designed for the Use of Practitioners and Students. By Francis H. Williams, M.D. Third Edition. The Macmillan Co., New York.

We have had occasion to commend this work in unmeasured terms. It has been up to within the last year the only work of its kind and remains the leading book dealing with the general use of the X-ray in medicine and surgery. The third edition the author considers a report of progress rather than a final presentation and the book has been largely rewritten and special chapters on the X-rays as a therapeutic agent added. Treatment of diseases of the skin and new growths is further presented and there is finally added a bibliography of recent work with the X-ray.

Any one who does anything whatever with the X-rays will find this work invaluable and for those who have never utilized this important aid in diagnosis and therapeutics they neglect their opportunities in not having a work of this kind.

A Treatise on the Care of the Expectant Mother, During Pregnancy and Childbirth and Care of the Child from Birth until Puberty. By W. Louis Howe, M.D. F. A. Davis Co., Philadelphia.

This is all told in 64 duodecimal pages. The book consists of short paragraphs that would be very useful to the young mother. There is very little that is new in the book, as would naturally be supposed, the author disclaiming any originality, his object being to put the expectant mother on a common-sense footing as to her condition, the care of herself during the period of pregnancy and the care of the child after birth. As to the care of the child after puberty the instruction is very inadequate.

The Care of the Baby. A Manual for Mothers and Nurses. By J. P. Crozier Griffith, M.D. Third Edition. W. B. Saunders & Co., Philadelphia, New York and London.

There have been many books published within the last two years on the care of the baby. Dr. Griffith's has the distinction of having been one of the very first in this field and in its present third edition it reflects ripened judgment not only from the standpoint of the pediatrist but from that of the book writer.

Very little need be added to our previous reviews of this work. The present edition differs from the previous ones in that it has been thoroughly revised, carefully rewritten and a large number of illustrations have been added. It is, we believe, one of the very best of the popular works that can be recommended by the profession to the laity.

Materia Medica and Therapeutics. By A. A. Stevens, A.M., M.D. Third Edition. W. B. Saunders & Co., Philadelphia, New York and London.

This text-book of Dr. Stevens was a very popular one on its first appearance. It has now been thoroughly revised, reset, and brought to date so that at the present time it represents a very handy and convenient text-book on materia medica and applied therapeutics.

It is not expected to be a monograph on physiological action, but represents a carefully condensed account of what is sound in our knowledge of this branch. It can be cordially recommended to the beginner in materia medica.

A Thesaurus of Medical Words and Phrases. By Wilfred M. Barton, M.D., and Walter A. Wells, M.D. W. B. Saunders & Co., Philadelphia, New York and London.

It was a happy idea, this, of the author's, to give us a medical thesaurus. It is the only one published and for every doctor who does any writing at all or reading, who desires to hunt out synonyms and antonyms the work will be invaluable.

It is not an encyclopedia nor a dictionary, but is a convenient handy volume for reference along the lines indicated.

We wish for it a very cordial reception.

Uric Acid as a Factor in the Causation of Disease. By Alexander Haig, M.A., M.D., F.R.C.P. Sixth edition. P. Blakiston's Son & Co, Philadelphia.

It is a very pleasant thing indeed to ride a hobby and the mental strabismus that results from a ten years' uninterrupted round the ring performance is well shown in this bulky book of Dr. Haig's.

We believe that it will not be many years before the uric acid hypothesis will be laid on the shelf and Dr. Haig's work be considered another monument to the ignorance of the times. In saying this, however, it should not be forgotten that the uric acid hypothesis of which Dr. Haig has been the most consistent originator, supporter and augmenter, has played a very definite and useful rôle in the study of disease processes. We have not the slightest doubt that the zealot's zeal of the author and his followers focused the attention of all practitioners on the desirability of a careful study of perverted metabolism and laid the foundation of much useful knowledge.

It is sometimes necessary for a false prophet to arise in order that great truths may be learned. Dr. Haig's uric acid hypothesis has served its day. If in the seventh edition Dr. Haig should cut his work down to 200 pages and tell us really what is worth knowing about the relationships of disease to disturbed proteid metabolism, taking the occasion to consider the work of physiological chemists who work in laboratories as well as in clinics, he would confer a great favor on the profession, but we fear that he has ridden his hobby so long that he is incapable of distinguishing between fact and error.

Turning to the book in critical manner, we can not feel but almost every page contains some misstatement. The chapter on uric acid and the circulation being a perfect jumble of disconnected erroneous statements or half truths that a really scientific man should be ashamed to put forth in this day as facts.

The Exact Science of Health Based upon Life's Great Law. By Robert Walter, M.D. Vol. I. Principles. Edgar S. Werner Publishing Co., New York.

This is an interesting work of 302 pages, dealing with a side of science that the doctor rarely considers. In fact he is so busy with the ordinary routine of his day's labor that he does not have time to discuss, much less read about, some of the philosophical principles related to the phenomena of the nature of disease and the processes of cure.

Life's great law, as defined by the author, recognizes that "every particle of living matter in the organized body is endowed with an instinct of self-preservation, sustained by a force inherent in the organism, usually called vital force, the success of whose work is directly proportioned to the amount of force and inversely as the degree of its activity."

The author then goes on to discuss the "constitution of nature," "heat and light," electricity and magnetism being considered as incident forces.

Transmutation Fallacies, Vital Science in its Relation to Philosophy; Life, its Nature and Source, Life's Secondary Laws, Social and Scientific Paradoxes; Health and Disease; Good Health and How to Regain it; The Vital Reservoir and How to Fill It; Vital Development and How to Secure it, are all chapters in this interesting résumé.

As this volume is but the first of a series, the author has not completely elaborated his argument, and we must wait for a second volume to pass judgment.

Disease of the Pancreas, Its Cause and Nature. By Eugene L. Opie, M.D., Associate in Pathology in Johns Hopkins University; Fellow of the Rockefeller Institute of Medical Research. J. B. Lippincott Co., Philadelphia and London.

The pancreas has remained one of the last of the organs of the body to yield up its secrets. Owing to a number of special conditions connected with its shape, size, location, its color and consistency, and its rapid disintegration, there is no organ of the body the pathological changes in which are more difficult to recognize and when recognized more difficult of interpretation.

The structure and functions of the gland are very little known and it is especially appropriate that a work of this kind should be presented, summing up our knowledge of the diseases associated with changes in the pancreas.

No one in this country can speak with more authority than Dr. Opie and we congratulate him on the excellent work here presented. We commend it most heartily to the attention of the profession and trust that with this introduction our lack of knowledge of pancreatic diseases may no longer remain an opprobrium in medicine.

# THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. 83. NEW YORK, SATURDAY, AUGUST 29, 1903. NO. 9.

## ORIGINAL ARTICLES.

### EXTIRPATION OF THE URINARY BLADDER.

BY FRANK HARTLEY, M.D.,

OF NEW YORK;

ATTENDING SURGEON, NEW YORK HOSPITAL.

THIS has been necessitated by (1) malignant growths, involving the organ primarily or secondarily; (2) tuberculosis; (3) exstrophy; (4) uretero-vaginal fistulæ following extirpation of the uterus (a few instances) (Harnleiter-Scheiden fistulæ, *Schweitzer Correspondenz*, No. 4, 1901); (5) fibroids of the uterus (one instance) (*Am. Gyn. & Obstet. Journal*, Morten XVI, 1900).

Malignant tumors which have required complete removal of the bladder have numbered, so far as I am aware, 23. Eleven cases were performed with intestinal implantation of the ureters (Maydl). There were six deaths, as follows: two from shock, one from pyelo-nephritis on the sixteenth day—failure of implantation, one from uremia on the fifth day, one from failure of implantation and death from sepsis and uremia—fourteenth day, one from pyelo-nephritis antedating the operation.

Seven operations were performed with vaginal implantation of the ureters. There were two deaths, one from collapse twenty hours after operation; the other from septic peritonitis on the ninth day. Two operations were performed with urethral implantation of the ureters. There were two deaths, one from shock, the other from uremia. Two operations were performed with skin implantations of the ureters (abdominal wall). There was one death from shock. One operation was performed with one intestinal and one skin implantation of the ureter from which the patient recovered (Dr. G. Woolsey).

The recoveries were 12 out of 23 cases, or 52.17 per cent. One patient lived eight years and nine months; one lived three and a half months and died from an unknown cause; one lived four months and died from pyelonephritis; one lived seven months; one three years and six months; one three years, and one lived two years. These last four were lost sight of. Five patients died during the operation, but no subsequent account is given of them.

The deaths were 11 out of 23 cases, or 47.83 per cent. Among the causes of death, uremia figures twice; shock, five times; failure of union of ureters with the intestine, sepsis and uremia, twice; pyelonephritis antedating operations, once; septic peritonitis, once. In comparing these cases with those in which a part of the bladder has been removed and one or both ureters so involved as to require their implantation into other portions of the reconstructed bladder I can find 12 cases of the latter condition with 7 deaths, or 58.33 per cent., and 5 recoveries, or 41.67 per cent. Of the 5 recoveries, 3 had recurrences in 3, 5 and in 14 months. In one case the patient was free from recurrence at three months from the time of the operation. In the remaining case, death occurred two months after operation from croupous pneumonia (*Archiv für klin. Chir.*, XXII).

Of the 7 deaths, 3 died of collapse following operation and 4 died a few days after operation. In 3 of the latter, the ureters were dilated and the patients died of collapse and syncope. In the fourth case death was due to sepsis following phlegmon of the pelvic connective tissue. Hence, when the ureters are implanted elsewhere than into the bladder and the bladder is removed, the recoveries are 52 per cent., and when the ureters are implanted into the reconstructed bladder the recoveries are 41.67 per cent. This difference in favor of the complete cystectomy seems due to two causes: (1) Vaginal implantations of the ureters where the recoveries have been the greatest in number. (2) The non-involvement of the ureters by the malignant process and the absence of secondary inflammatory process in the ureters.

The very best results as to the freedom from recurrence are seen in the cases where the bladder is involved secondarily to an adjacent organ (uterus) and the ureters have been implanted into the vagina. In these cases the recoveries have been 71.5 per cent., the mortality 28.5 per cent.

The total extirpation of the bladder with the implantation of the ureters elsewhere than in the vagina gives 43.75 per cent. of recoveries and 56.25 per cent. mortality. These results are quite as good as the partial extirpation of the bladder with implantation into the reconstructed viscus, viz.: Recoveries 41.67 per cent.; mortality 58.33 per cent. The so-called cures in complete extirpation make a better showing than in the partial operation; whereas in the former several cases are reported as free from recurrence at four, seven and ten months, two years and eight and three-quarter years, in the latter of 5 cases recovering from the operation recurrences took place at three, five and fourteen months, respectively, in 3 cases. In one case death took place from pneumonia at two months. One case was free from from recurrence at four months.

It follows, then, that if the ureters and the bladder are involved, the complete extirpation of both and the implantation of the ureters into the vagina gives the best results both as to recovery and freedom from recurrence. This method, however, gives the patient no control over the urine and requires the constant use of the cathe-

ter under the best conditions. If the patient be a male, I believe complete extirpation of the bladder is the proper procedure; but whether we should implant the ureters into the urethra or the skin and wear a urinal, or should implant them into the intestine with rectal continence is still a question not settled.

So far as cases go, the results of intestinal implantation give 6 deaths in 11 cases—54 per cent. mortality—in which 2 died of shock, 1 of uremia on fifth day, 1 of failure of anastomosis and sepsis, 2 of pyelonephritis antedating operation. The results of the urethral and the cutaneous implantations give 3 deaths in 5 cases—60 per cent. mortality—in which 2 died of shock and 1 of uremia.

The choice for the method of dealing with the ureters in the male offers but little advantage one over the other. What is offered seems to be in favor of the urethral or cutaneous implantations, since the deaths were due in large measure to avoidable causes.

The second cause for extirpation of the bladder has been tuberculosis of that organ. Tuberculous ulcers of the bladder have been greatly benefited and some have been cured by suprapubic drainage. Such cases have been reported by Curtis (*Annales of Surgery*, 1895), Powers (*Annals of Surgery*, 1902) and Cheyne (*Lancet*, June and Oct., 1895). By hygiene and climatic treatment other ulcerations have been reported as healed by Bolton Bangs (*Annals of Surgery*, Oct., 1895), and by Gordon (*Dublin Journal*, May, 1899). In other cases of ulcerations of this variety excision or destruction of the ulcer has proved successful (Strauss, *Wiener medicinische Wochenschrift*, No. 51). In another class of cases in which the process is extensive, extirpation of the bladder has been resorted to, as a cure, by Martin (*Amer. Gyn. and Obstet. Jour.*, 1900, xvi, pp. 395-429); by Carl Beck (*Annals of Surgery*, 1899, p. 186), and by Trendelenburg (*Verh. den D. G. für Chir.*, 1895). In one case, the mucous membrane of the bladder, together with the ulcers has been removed and has been reported as curative (Delagénière, *Bulletin et Mem. de la Societé de Chir.*, 1895, p. 251).

All of these methods have had their successes. In no one method can the importance of hygienic and climatic treatment be neglected. The case I wish to report is one which required more than local treatment and rest by drainage. It was one which in my judgment could not be cured without a cystectomy. This history is as follows: Mary T., admitted to New York Hospital on April 19, 1902. Discharged June 9, 1902: clerk, U. S.; age, eighteen years. Previous history revealed no personal history of tuberculosis, but two uncles died of consumption. She had measles when a child, and one year ago had pleurisy and pneumonia. No venereal history. Present illness began three years ago when frequent micturition and burning pain in the bladder occurred. Three years ago a vesicovaginal fistula was made. This gave some relief, but was very annoying. Two years ago she had this fistula closed but the old symptoms, frequent micturition and burning pain gradually returned so that within six months her condition was unbearable. One year ago a suprapubic cystotomy was performed, and with this drainage and local treatment she was again relieved in part, but not entirely. After six months of drainage she again submitted to an operation, closing the suprapubic wound. As soon as this was closed her former frequent micturition returned. She has at present constant burning pain, frequent micturition and at times slightly bloody urine. There is constant pain and increased sensitiveness over the external genitals and the bladder. The external genitals are not observably congested. There are two bed-sores upon the buttocks from the constant contact with the urine. Her general condition seems good.

The physical examination of the thorax and abdomen is negative. The examination per rectum reveals nothing but an excessively sensitive bladder. A cystoscopic examination reveals a chronic cystitis and ulcerations upon the base and posterior wall of the bladder. The urinalysis shows the urine to be cloudy, alkaline, yellow, 1.018, albuminous; no sugar, mucus, leucocytes or tubercle bacilli. Diagnosis was then made of tuberculous ulceration in the bladder. Since the ulcerations involved the base and posterior wall of the bladder and were not seen at the urethral orifices this tuberculous process was probably of vesical origin (at least not renal). An exploratory operation was agreed upon for the purpose of excising the ulcers, or dissecting away the mucous membrane, or, as a last resort, the extirpation of the bladder. The patient readily agreed to this suggestion.

The operation was performed April 28, 1902. A vertical incision, four inches in length, was made, extending from the lima alba to the peritoneum. The cavity of Retzius was entered and the peritoneum was raised from the abdominal wall and from the fundus of the bladder. A generous incision was then made through the fundus of the bladder and its interior inspected. The base and greater portion of the posterior wall was seen to be covered with small ulcerations, extending into and through the mucous membrane. Some areas were devoid of mucous membrane and the bases of the ulcerations were covered with dirty-grayish sloughs. Beneath the bladder, at the base near the left ureters two or three small glands were felt through the bladder wall. Beneath the ulcerations, upon the posterior wall of the bladder, the tissues are much thickened and did not glide upon one another. The mucous membrane about the urethral orifices seemed swollen but healthy and unbroken. It did not seem possible to remove the ulcerations without perforating the bladder wall, nor did it seem possible to excise the base of the bladder and leave the ureters. The only possible outcome appeared to be to anastomose the ureters with the rectum or vagina after the complete removal of the blad-

der. As the ureteral orifices seemed healthy, and the disease could not be thoroughly removed without sacrificing over two-thirds of the bladder, and that at the base and posterior surfaces. I decided to remove all of the bladder except that immediately surrounding the ureteral orifices (a circle of three-fourths of an inch in diameter). This being the case I could unite the bladder wall and mucous membrane surrounding the ureters to one another and then implant them by the Maydl method, or I could implant them separately by Pozzi's method. I preferred the intestinal to the vaginal implantation, because of the favorable results following this method in extrophy of the bladder, both as concerns the infection of the kidney and the tolerance of the urine by the rectum. Sufficiently prolonged and careful treatment had been carried out in this city in three of our hospitals and under the best observers, so that no hesitancy was felt in the necessity of this step.

Acting upon this decision, the peritoneum was carefully stripped from the fundus and the posterior surface of the bladder until the ureters were recognized and the base was exposed to view. This was accomplished with surprisingly little hemorrhage. Each ureter was now divested of its connective tissue attachments in the broad ligaments, care being taken not to interfere with its nutrition by stripping the ureters too closely. When they were dissected so as to move freely, the bladder was removed, leaving each ureter surrounded by an irregularly shaped piece of bladder wall three-fourths by one-half inch. These two pieces of bladder wall were trimmed and sutured together preparatory to suturing them into the sigmoid flexure (Maydl's method). The peritoneum was now opened by a vertical incision, passing from the fundus of uterus upward two inches. The sigmoid flexure was drawn through it sufficiently to allow its being clamped above and below the point of implantation.

A vertical incision was now made in the intestine and the ureters with their surrounding (1 cm.) of bladder wall were implanted. The mucous membrane of the bladder and that of the intestine was sutured by interrupted silk sutures. The serosa of the intestines was sutured to the connective tissues and muscular coat of the bladder by another row of silk sutures. This union of the sigmoid and ureters would undoubtedly be pressed upon by any enlargement of the uterus and to avoid such pressure a transverse incision was made upon each side at the lower angle of the vertical one in the peritoneum and through these slits which passed through the peritoneum of the broad ligament the ureters were displaced backward and outward allowing the uterus to appear between them. This was accomplished without difficulty. The vertical and lateral peritoneal incisions were now closed. At this time the glands, which were felt to be near the left ureter when examining the interior of the bladder with the finger, and which we carefully avoided when loosening the left ureter in the broad ligament were extirpated. The abdominal wall was sutured and a small strip of rubber drainage placed in the cavity of Retzius. The wound was dressed aseptically. A No. 30 catheter was inserted into the rectum.

April 19. Temperature, 99° F.; respiration, 24; pulse, 100. April 20. Slept half of the night. April 21. Pain in the rectum; urinalysis, yellow, cloudy, alkaline, 1.018; albumin; no sugar; mucus; leucocytes. April 28. Patient complained of much pain in the wound. Little urine has been caught by the tube. She is restless, with a pulse of 136, and a temperature of 97° F. The drainage in the cavity of Retzius was removed and as nothing was seen, a posterior vaginal section was made. No leakage had taken place either into the peritoneal cavity or into properitoneal space. Urinalysis, smoky, yellow, turbid, alkaline 1.008; albumin, a trace.

May 1. Rectal tube removed. Urine passes involuntarily, caught in napkin; rectum irrigated regularly, three times per day. May 2. Patient sleeps well; holds urine about two hours; rectal irrigation of six hours. May 6. Sutures removed. May 10. Same treatment. Urinalysis, yellow, cloudy, alkaline, 1.010; albumin, a trace; no sugar, mucus; detritus microscopically negative.

May 15. Retained 18 oz. urine
1 oz. urine
18 oz. urine
} Three passages during the day.

May 17. Retained 16 oz. urine
1 oz. urine
16 oz. urine
} Three passages during the day.

May 19. Retained 18 oz.urine
13 oz. urine
} Two passages during the day.

May 30. Urine is made three times daily and once or twice at night.

June 6. Discharged cured.

*Specimen.*—Represented by a piece 9x4 cm.; deeper layers of the bladder wall apparently normal. Mucous membrane shows many ulcerated areas, with a marked chronic cystitis. The glands removed show tuberculous involvement. Diagnosis, chronic cystitis; tuberculous ulceration.

January, 1903.—This patient presented herself at the New York Hospital, Jan. 10. She is in good health, is employed all day as a clerk. Makes water three to four times during day and once or twice at night. Urine collected from the rectum shows it to be alkaline, cloudy; 1.010; a trace of albumin; no sugar; mucus; detritus. Microscopical examination is negative.

The third condition demanding at times a removal of the bladder is exstrophy of the bladder. My views upon this subject have been fully enunciated in the *Annals of Surgery*, July, 1901. At that time, among other cases, I related the history of a patient three years of age, operated upon on Feb. 22, 1900, for this malformation, in whom the bladder was removed and the ureters

implanted in the upper portion of the rectum. On March 27, 1901, the patient was in good health, with no renal, or rectal irritation or tenderness. The urine was passed every four hours. At night once unless the child neglected it before going to bed. On June 30, 1901, this patient died in a hospital in Philadelphia. The cause of death is stated to be "enteritis." I have not been able to obtain more knowledge of the case.

At the same time I gave the history of another patient operated upon by me in 1894 at the Roosevelt Hospital by the method of superimposed skin flaps, and again in 1899, at the New York Hospital. The second operation for closure of the urethra by Küster method failed. In consequence of this failure the patient was advised to return to the hospital within six months for a radical operation consisting in either the removal of the bladder with implantation of the ureters by the Maydl or Pozzi method or by rectovesical anastomosis of Frank. For this radical procedure he entered the New York Hospital Nov. 5, 1902. Patient is now eighteen years of age.

Operation occurred Nov. 6, 1902. A median incision in the abdominal wall was made which exposed the peritoneum above the bladder. Enucleation of the bladder which was difficult on account of the vascularity and the old scar tissue formed seven years ago. The bladder was removed, except a piece of the trigone 1½ by ½ inch, including the orifices of the ureters. The peritoneum was now incised and the suture of the sigmoid and the bladder wall containing the ureters was made with two rows of silk sutures, as in the previous case.

Abdominal wall sutured; prevesical space drained with gauze; rectal tube inserted; urine collected during day, 44 ounces. Nov. 7, dressed, 32 ounces. Nov. 8, patient complained of epigastric and lumbar pain on right side. Bowel irrigated. Urotropine grs. x q. i. d. Urinalysis brown, 1.012, alkaline, considerable albumin; phosphatic crystals; mucus, 53 ounces; Nov. 9, urine, 36 ounces; Nov. 12, 26 ounces; Nov. 13, 48 ounces; Nov. 14, 37 ounces; Nov. 15, 35 ounces; Nov. 16, 64 ounces; Nov. 26, discharged, cured.

For exstrophy of the bladder, the extirpation of the viscus with the implantation of the ureters into the sigmoid flexure or the rectum has been performed 46 times with a mortality of 15 per cent., 6.5 per cent. of this represents infection of the ureters and kidneys occurring immediately after or at a remote period from the operation. In how many cases the infection of the ureters and kidney has antedated the operation cannot well be obtained owing to the failure of the proper urinary examinations. 8.5 per cent. represents shock, a condition which may be avoided by improved technic and a better selection of cases.

Of these 46 cases, 1 case was seen four months after operation; 15 cases were seen one year after operation; 13 cases were seen two years after operation; 9 cases were seen three years after operation; 1 case was seen seven years after operation.

The best methods of treating this condition, provided the construction of a continent bladder is impossible, seem to be (1) cystectomy with the intestinal anastomosis of Maydl or Pozzi. (2) Vesicorectal anastomosis (Frank). (3) Extirpation of the bladder and urethral implantation of the ureters (Sonnenberg). (4) Extirpation of the bladder and vaginal implantation of the ureters (Pawlik).

The remaining conditions for which extirpation of the bladder has been performed are rare and have not come under my observation. Were such cases presented it is to be observed that the intestinal anastomosis presupposes intact ureters and gives rectal continence, whereas the vaginal implantation gives slightly better results, but without urinary continence and requires the use of a urinal.

52 West Fiftieth Street.

## THE PROGNOSIS OF TABES: AN ANALYSIS OF 140 CASES OF LOCOMOTOR ATAXIA.*

BY JOSEPH COLLINS, M.D.,
OF NEW YORK;
PROFESSOR OF NERVOUS AND MENTAL DISEASES IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; VISITING PHYSICIAN TO THE CITY HOSPITAL; CONSULTING NEUROLOGIST TO THE HOSPITAL FOR RUPTURED AND CRIPPLED.

When discussing the symptomatology of tabes I called attention to the variability of its clinical manifestations. The course of the disease in different individuals is one of the most remarkable things about it. One patient will have it for ten years and be made aware of it only by lancinating pains, impaired sexual vigor and occasional nocturnal incontinence of urine. Another develops hypotonia and ataxia so rapidly that he becomes bedridden a few months after the onset of subjective symptoms. The symptoms of tabes are customarily said to display themselves in three stages which constitute the course of the disease: (1) The preataxic stage; (2) the ataxic stage; (3) the profoundly incoordinate and hypotonic stage, often spoken of as the paralytic stage, but in reality there is no actual paralysis save exceptionally and then it is to be considered a complication.

The duration of these three stages or periods can only be approximated, it varies so enormously in different patients. We have no means of estimating how long the disease, as evidenced by unequivocal signs, has been in existence when the patient comes under observation. For instance, in the following case the disease may have been present for many years. A woman, thirty-eight years old, who married at twenty-one years of age, but who had never borne children said that for four years before coming to see me she had rheumatism from the toes to the waist line. It was never very severe but sometimes for a few days at a time it would require medicine from her

* Part I of this series was published in the Medical News, Jan. 3, 1903; Part II March 7 and 14, 1903; Part III June 13 and 20, 1903.

physician. The symptom for which she consulted me was a "sore, sensitive sensation" in the left leg and a numbness of the legs which was gradually crawling up to the thighs. Examination showed Argyll-Robertson pupils, loss of knee and ankle-jerks, hypotonia, hypesthesia and hypalgesia of the legs, especially of the outer surfaces. There was no complaint of incontinence of urine, girdle sensation, paresthesia, disturbance of gait or station, or diplopia. The diagnosis of tabes in such a case can be made with as much positiveness as if ataxia were one of the symptoms.

Babinski (*Revue Neurologique*, Jan. 15, 1902, p. 59) has related the case of a woman, sixty-five years old, who consulted him for some trivial affection and who presented inequality of the pupils, Argyll-Robertson phenomenon, and absence of the Achilles-jerks, objective symptoms which led him to make the diagnosis of tabes. On inquiry he satisfied himself that some of these symptoms had dated from the patient's twentieth year. In other words, the disease had existed in a benign way for forty years.

To date the beginning of the disease from the onset of symptoms noted by the patient would often give us very unreliable information on this point. I have the histories of a number of patients in which the diagnosis of tabes is certain, although there are no symptoms which the patients consider to be those of tabes. For instance, a man, fifty-five years old, came to see me on October 22, 1902, and said that the morning before on arising he found that he could not open the right eye and when the lid was lifted with the finger that he saw double. Examination showed ptosis and paralysis of all the eye muscles save the superior oblique and external rectus, the pupil being widely dilated and unresponsive to light. Examination showed in addition to this exaggeration of the knee-jerks, normal ankle-jerks and tachycardia. December 28, 1902, all traces of the ptosis and ocular paralysis had entirely disappeared. In the meantime he had been having bichloride of mercury hypodermically, one-third of a grain every second day and iodide of potash, 90 grains a day. June 1, 1903, examination revealed Argyll-Robertson pupils; distinct Rombergism; sluggish ankle-jerks; left knee-jerk exaggerated, right diminished; distinct hypesthesia over both peroneal surfaces; incontinence of urine nocturnal and diurnal. Such association of symptoms leaves no doubt as to the diagnosis of the disease.

In contrast to these cases, I may refer to the following case to illustrate the rapidity with which the disease occasionally overwhelms the patient. Mrs. B., married, has borne three children and one miscarriage. There is no history or indication of syphilitic infection. She maintains that she was well and had been so on September, 1902, when she stepped on a banana skin and fell to the sidewalk striking the right leg. Apparently she was not injured for she got up and went along. That night the leg felt sore, but after having it rubbed with alcohol it felt better. The next day she went to work but felt nervous and "shaky." The following day she was so nervous and had so much pain in the leg that she had to leave off work. The pain which was in both legs, but more in the leg that was injured when she fell than in the other, increased for a few days and then went away. She then noticed that she could not walk steadily and this grew gradually worse until at Christmas time, *i.e.*, three months later she was so unsteady in her gait and uncertain in her step that she could not go out unattended. When I first saw her, six months after the onset of the symptoms, she had no complaint of any sort to make save of difficulty in standing and walking. The ataxia which she presented, both of station and locomotion, was very profound and she could walk only when aided by another person and could stand only when holding something. On attempting to go downstairs and frequently when walking through the room there was sudden giving way of the knees. The knee-, ankle- and elbow-jerks were absent, the plantar-jerk was present, not lively, and of the flexor type. The pupils were equal, of moderate size and unresponsive to light but quickly responsive to accommodation. There was no anesthesia or analgesia of any part of the body. She says that the prick of a pin is felt more distinctly over the upper part of the thorax than over the middle and lower, but in reality there was very little difference. There was no girdle sensation, diplopia, incontinence of urine, hypotonia or trophic manifestations. In other words, the case is distinctively an example of the motor type of tabes which I have already described (See Case 7, Medical News, March 14, 1903).

The length of time that elapsed between the first symptom of the disease and the appearance of ataxia in my 140 cases, was three years and five months. These figures may be very misleading. In the first place patients seen in the hospital for the first time a number of years after the beginning of the disease have very little idea when the disease really began or what period intervened between the first symptom of tabes and the ataxia. Then again a few cases like that last related in which ataxia is an early symptom makes the average duration of the preataxia stage appear much shorter than it usually is. I am inclined to believe that the preataxia stage of tabes in all cases save those of the motor type is oftener above five years than below.

The average duration of the disease is difficult for me to estimate as I have been in the way of seeing many cases of the disease only during the past ten years. Of the 140 cases that I am here analyzing, 11 have died and the average duration of the disease in these cases was thirteen years. This does not actually show the duration, for four of these cases died of intercurrent diseases. One from acute Bright's disease, two from tuberculosis, one from probable rupture of an aneurism and one from suppurative peritonitis from rupture of an abscess.

The matter that interests us as physicians, and

our patients with locomotor ataxia, is, What can we tell them from a consideration of the symptoms and signs of their disease about their future. Can the wage-earner be assured that he will be able to provide for his own needs and those of his family for a certain length of time and if so, how long will it probably be. Shall the man of affairs be counseled to continue the direction of his business or shall he, when he learns that he is suffering from an incurable disease, relinquish his work and prepare for translation? In brief, what are we able to tell a person after we have diagnosticated tabes of what the future has in store for him. He is no longer interested in the etiology of the disease and even though he might be, what we have to tell him on that score only adds to his misery.

The factors that influence the prognosis are: (1) The clinical type of the disease; (2) what may be called the anatomical type of the disease, *i.e.*, whether of the lumbar or lumbo-dorsal cord (the customary location) or of the cervical or cervico-bulbar region; (3) sex and age; (4) the individual, his occupation and the treatment.

Next to these cases the prognosis is most favorable in the cases that I have referred to as the motor type and this is especially true since the introduction of the Fraenkel system of exercises and the more general utilization of orthopedic apparatus. The outlook in this class of cases is best when symptoms of involvement of the sympathetic nervous system are not profound. On the other hand, it is unfavorable when severe disturbance of the urogenital system and trophic symptoms are early and conspicuous manifestations. It is in cases of this sort that certain health resorts or certain therapeutic measures get a reputation for "curing" tabes which is wholly undeserved. I have notes of a patient of this sort who is convinced that the treatment of Lamalou is responsible for the very considerable recovery which he has made. It does not alter his opinion of the efficacy of the treatment of Lamalou for tabetics to know that I have notes of a dozen patients who have not been particularly benefited by repeated visits to this favorite French resort. I have seen patients having this same type of the disease benefited from the combined effect of wearing a pair of shoes for which he paid $3,000 and the emotional exaltation which he got from coming in contact with an individual who had the assurance to ask that amount for them, and I have seen them get entirely well functionally under a treatment of rest and graduated exercises. As an example of this I may refer to the history of a young lady quoted in the article on Symptomatology. When she first came under treatment she was able to walk only when steadied and supported on either side, but within two years she had returned to her work on the stage, which necessitated dancing. She is now apparently quite well, the only symptoms being incontinence of urine and loss of sexual desire. The signs of tabes are still unequivocal.

The clinical type of tabes which in my experience has the least favorable prognosis is that in which disturbance of the sympathetic nervous system predominates; vesical symptoms, crises, trophic manifestations in the soft and hard tissues. Cases in which the bladder and rectum are involved early and severely, often pursue a rapid course little influenced by treatment. Moreover incompetency of the bladder often opens the road to complications such as cystitis and pyelitis and their consequences which not only add to the patient's suffering and depreciate his vitality, but may directly or indirectly cause death. Although death rarely occurs during tabetic crises of one kind or another, they gloomify the prognosis through the exhaustion which they produce and by reason of the fact that patients who suffer from them are liable to become victims of morphine. I have pointed out in another article ("Tabes and Progressive Muscular Atrophy," *Journal of Nervous and Mental Disease*, June, 1903) that tabes when associated with profound atrophy of the muscles of either neural or spinal origin is apt to be atypical in its clinical delineation and to run rather a rapid course. I have not noted that the occurrence of the milder forms of atrophy influences the prognosis. They may do so by incapacitating the patient from getting about and by impairing the vital resistance of his tissue to infections such as tuberculosis, pneumonia and erysipelas. The same statement holds true, I think, for the arthropathies.

In 1881, Benedikt, of Vienna, in writing of the prognosis of tabes, made the statement that the clinical form of the disease in which the prognosis was far more favorable than in any other was tabes with atrophy of the optic nerve. A few years later he maintained that it was a rule without exception that the motor symptoms of tabes recede as optic atrophy progresses. Since that time a number of writers have published cases which, in a measure at least, substantiate his first statement. Dejerine (*Societe de Biologie*, June 22, 1889) particularly maintaining that it is rare to find a blind tabetic who presents the signs of the second stage of tabes, and that in the majority of cases the advent of blindness is coincident with an amelioration or cessation of pains. My experience is entirely at variance with these views and with one exception, possibly two, I have never seen the course of the disease modified in any way by the advent of blindness. So far as the appearance of ataxia in amaurotic tabetics is concerned, I have a patient under observation now, as he has been for the past seven years, who did not become ataxic until two years after blindness was complete. It must not be forgotten that ataxia is itself a late manifestation in a large proportion of cases, while optic atrophy is comparatively an early one. The disease exists for years in many cases and is to be diagnosticated from the symptoms and the signs long before ataxia sets in, and all clinicians seem to be agreed that if optic atrophy does not set in in the earlier years of the disease it is not likely to occur at all. If blindness occurs in a benign case of tabes it may

well be seen that the occurrence of blindness has an apparent ameliorating effect upon the disease, but that it has any real effect to alter its course I am unwilling to believe. This connection is a favorable one, to refer to some views emitted on the subject of tabes with blindness by Marie and Switalski at the International Medical Congress at Paris in 1900. They attempt to distinguish two varieties of tabes with blindness: (1) Tabes with papillary atrophy and (2) the papillary atrophy of tabetics. Under the first they classify patients who have all the phenomena of tabes, often to a very pronounced degree, with ataxia, Rombergism, and serious disturbances of nutrition. Under the second the clinical aspect is very different, the patients are well nourished, with the appearance of health and there exists no trophic trouble. The clinical symptoms of tabes, *i.e.*, the pains, the ataxia, and the vesical trouble show themselves to a very slight degree. From a nosological point of view they believe that we are probably not concerned with an essentially distinct morbid species in these two forms of tabetic blindness because the etiology of both is the same, viz., syphilis, but that there is a different localization of the same process, or perhaps even of a different process, at the basis of it. Although the wisdom of such an attempt at classification or subdivision is very doubtful, nevertheless we encounter cases which correspond with it. I do not recall whether there are any autopsies recorded upon the second class of cases mentioned by these writers. Unless there are, and the findings in the cord correspond to those of tabes, it may be considered questionable whether the form of disease described under (2) should be admitted under the heading of tabes at all.

I have encountered three such cases during the period that 153 cases have come under observation. The last patient that I saw is so typical of this variety that I shall quote it here. Mr. T., fifty-seven years old, an actor, had syphilis when about thirty years of age. For this disease he was treated for about one year with mercury and iodide of potassium. A few years after the syphilitic infection he had a very mild attack of iritis. Aside from this he remained well until he was forty-seven years old. He came home from the theater one night in his usual health, went to bed and to sleep. About 2 A. M. he was awakened with a boring sharp pain in the chest. This continued for several hours and then gradually passed away. After it ceased he had a sensation in the eyes as if they were dancing and when he tried to get up he felt giddy. As the result of all this and of the pain in the chest and in the epigastrium, which recurred every now and then, his nerves gave way and he had what he calls an attack of "nervous prostration" which lasted five weeks. During most of this time he was confined to bed. When he tried to stand his legs bent beneath him. No other details of this illness can be got save the trouble with his sight which began at this time. He says that everything that he looked at kept dancing before his eyes. From that time his sight began to fail progressively and continued until a year ago when he became entirely blind. His account of the way in which the vision failed is so characteristic of tabetic amaurosis that it deserves to be quoted. During the first few years of failing sight he says he could see objects very well, providing he stopped and looked at them directly ahead, but if he wished to take in many objects at a glance it was very difficult, they were blurred and indistinct. In other words, he had to have the object fairly ahead of him and to focus steadily upon it. Gradually his sight became so affected that things that he focused had the appearance of being seen through the large end of a telescope. The visual field got steadily smaller and smaller until it narrowed down to a pin-point aperture. During these eight years when he was losing his sight he says that he felt fairly well save that at times he had sharp darting pains throughout different parts of the body and at times a sensation in the right thigh as if it were asleep. He has also had at times difficulty in passing water, occasionally he has to wait some time before starting the stream and to press hard in order to empty the bladder but he considers that his bladder performs its function well. He has had at times a girdle sensation around the lower part of the abdomen. He is still fairly potent.

Examination shows practically no ataxia of locomotion or station, there being slight unsteadiness when he stands on the left foot. There is no ataxia of the upper extremities. There is slight diminished keenness of sensibility from below the spine of the scapulæ to about the eleventh dorsal vertebra and extending around the body. The tendon-jerks are all very lively, the plantar-jerks, the cremaster jerks and the abdominal jerks are normal. The pupils are large and unresponsive to light. There is complete primary atrophy of both optic nerves. The left iris shows some indication of previous inflammation. The left ear gives evidence of nerve deafness.

One may consider the disease process in this patient a variety of tabes or he may not. If he puts it in that category it is clearly a very atypical case and one is not justified in making deductions anent the prognosis of ordinary tabes from it or from any number of such cases.

It was only by careful questioning that any symptoms whatsoever were elicited, and taken by themselves the symptoms so elicited have little diagnostic significance. The physical signs would not justify the diagnosis of tabes. Nevertheless, this may be taken as a fairly good example of amaurotic tabes. The point that I wish to make here is that from a prognostic point of view it is quite a different disease from ordinary tabes.

The prognosis is worse in cases of brusque onset. Although in many such cases the symptoms ameliorate, often the disease has incapacitated the patient, and although in some instances there is considerable restitution of function, in the majority of cases the disease pursues a rapid course especially if associated with symptoms indicating

profound disorder of the sympathetic nervous system.

The prognosis is far better in those cases in which the disease is of slow and insidious onset, than in those in which it has developed abruptly. It is incontestable that the longer the onset of ataxia is delayed the less grave is the prognosis. It is my experience that as the disease conforms itself in the beginning so does it continue to do during its entire course. The disease seems to advance more rapidly in patients in which tabes developed within a comparatively short time, say ten years after a syphilitic infection, than when it develops much more tardily and the prognosis is distinctly worse in these cases. One reason for this is that exudative lesions of syphilis in the blood-vessels and viscera may not only lower the patient's vitality and recuperative capacity, but mediate intercurrent conditions such as apoplexy which causes the patient's death directly. The prognosis is much more unfavorable in high tabes, cervical and cervicobulbar tabes, than in the common variety. Why encroachment of the oblongata by the disease process should make the prognosis grave is readily apparent. It adds the terrors and dangers of bulbar palsy. Death is very rarely caused directly by tabes, but by some such accident as the pneumonia of swallowing, syncope and pharyngeal paralysis leading to asphyxia.

Early involvement of the nerve supply of the larynx is an unfavorable symptom. I have seen one case in which this complication, occurring comparatively early in the course of the disease, caused paralysis of the adductors of the vocal cords which necessitated immediate tracheotomy to cut short an attack of asphyxia which threatened the patient's life. Another patient in which the outlook was grave because of the sudden onset of the symptoms and early development of laryngeal symptoms, was Case XI, recorded in the MEDICAL NEWS, March 14, 1903.

The course of the disease seems to be more rapid in women than in men. Out of 20 cases of the disease in women, only one was benign. Although this is too small a number from which to draw conclusions, benign cases seem to be frequent in males. The most brusque and rapidly progressive cases that I have seen have been in women and especially in those in whom no history or indication of syphilis could be obtained.

The disease seems to advance more rapidly in young tabetics under thirty-five years of age than in those who develop the disease later in life. At least that has been so in the patients under my observation. Another fact that has been noted about these cases in comparatively young adults, is that the disease after reaching a certain stage, oftentimes incapacitates the patient, the progress seems to cease for a long time and under treatment restitution of certain functions is brought about.

The prognosis is worse in those whose occupation necessitates standing or fatiguing use of the legs. Anything that contributes to leg weariness tends to facilitate the rapidity of the course of the disease. This is one reason why we encounter such a disproportion of comparatively recent tabetics in our large public hospitals. Their social and hygienic environment, intemperate use of spirits, and the necessity for earning their daily bread, all combine to make the course of the disease more rapid.

The prognosis of tabes to-day differs from that of twenty-five years ago because the disease has apparently undergone clinical transformation. We no longer see the type of tabes delineated by Duchenne, Romberg, Charcot, Seguin or any of the clinicians of the previous generation and to which the name "Progressive Locomotor Ataxia" seemed so apt and so descriptive. The symptoms are less severe, the course of the disease is less progressive and what may be called aberrant forms or forms "frustes" of the French writers are more common. I very rarely nowadays see in private or hospital practice, the very pronounced form of the disease which I saw ten or fifteen years ago. To be sure there are gathered together in almshouses and hospitals for incurables a few cases of this pronounced type.

What the explanation is of this change in the clinical delineation of tabes it is not easy to say, moreover, no one factor is entirely responsible for it. In the first place early and atypical tabes are recognized by the general practitioner and by the specialist so much more frequently to-day than they were even a few years ago, that this must, in a measure, account for the impression that many of us have received that the disease does not display itself as formerly. In the article on the symptomatology I called attention to the fact that objective symptoms of the disease are not infrequently present for years before the subjective symptoms. It naturally follows that if one encounters a number of these cases and has them under observation for a protracted time, and no very severe symptoms develop he becomes convinced that the disease is not the same as it used to be. On the other hand, it may well be that the treatment has had something to do with bringing about this condition. Although we are still in the lamentable position of having no specific for tabes and in fact, of having no medicament which we can say positively will alter the course of the disease, nevertheless we have learned empirically that conformation to a certain regime, mode of life, dietary, medical therapy, massage, hydrotherapy, climatotherapy and electrotherapy has not infrequently such influence upon the disease that the process seems to stop advancing while they are being employed.

---

**The Germ of Rabies.**—Dr. A. Negri, Golgi's assistant at Pavia, announced last March the discovery of the specific micro-organism of rabies. After further investigation he states that he has examined more than 100 dogs with natural or laboratory rabies, and has never failed to find the specific micro-organism in the nerve centers. On the other hand, he has never found it in other dogs.

## THE TOXIC ACTIONS OF UROTROPIN: WITH REPORT OF A CASE OF HEMATURIA AND HEMOGLOBINURIA FOLLOWING A DOSE OF SEVEN AND ONE-HALF GRAINS.*

BY WARREN COLEMAN, M.D.,

OF NEW YORK;

PROFESSOR OF CLINICAL MEDICINE, CORNELL UNIVERSITY; ASSISTANT PHYSICIAN TO BELLEVUE HOSPITAL.

Urotropin is an unstable chemical compound formed by the action of formaldehyde on ammonia. It is readily decomposed, with the liberation of free formaldehyde, by feeble acids and even acid salts, as acid sodium phosphate of the urine. Other trade names are aminoform and cystogen.

Nicolaier first employed urotropin in 1894 as a diuretic and uric acid solvent. Later he recommended it as a urinary antiseptic. He began its administration in doses of 120 to 150 grains a day, and even gave as much as 150 grains *at one dose* without ill-effects. But larger experience taught him that unpleasant symptoms might result from daily doses of even 90 grains. He has never seen, however, any ill-effects from daily doses of less than 30 grains. As urotropin came into general use, toxic effects were occasionally observed after as small a dose as 15 grains a day and, in the case which I shall describe presently, after a single dose of seven and one-half grains.

When one considers the extent to which urotropin is administered, the limited number of cases reported in which its use has been attended by toxic effects confirms the general belief in its freedom from such effects. Yet the fact that it may prove toxic, perhaps from idiosyncrasy, must not be lost sight of. It is the purpose of this paper to call attention to such toxic actions as have been reported.

Individuals vary greatly in their susceptibility to urotropin, and Keyes states that the same patient may vary in susceptibility at different times. Children bear urotropin well, though somewhat smaller doses should be employed.

Urotropin is sweetish, with a somewhat bitter after-taste, but when well-diluted is practically tasteless. All who have used urotropin agree that it should be freely diluted for administration—that a dose of 7½ grains should be dissolved in at least half a pint of plain or carbonated water at ordinary temperature, and larger doses in proportion—or irritation is likely to occur. In view of the large quantity of water to be taken with it, urotropin should be administered when the stomach is empty, that is, before or not till two hours after meals. Nicolaier and Richardson give urotropin after meals, but the majority of writers advise that it be given "morning and evening," which means, I take it, on an empty stomach.

*The physiological actions* of urotropin have not yet been definitely worked out, as is evident from the conflicting statements found in the literature. As has been stated, Nicolaier first recommended urotropin as a diuretic and uric acid solvent. Later he found it to be a powerful urinary antiseptic. The only other action that has since been attributed to urotropin is its power of correcting phosphaturia, as stated by Casper.

Urotropin is quickly absorbed, since its elimination by the kidneys begins within ten minutes after administration. The duration of its presence in the urine depends upon the size of the last dose. Nicolaier, giving 7½ grains, found that it disappeared in thirteen hours; with 22 grains, in twenty-seven hours; and he states that even after 90 grains per day, it soon disappears. Cammidge, giving 30 grains a day to a healthy adult, found urotropin in the urine for twenty-six hours. Nicolaier thinks Casper's observation that urotropin persisted in the urine for fourteen days after the last dose is probably erroneous.

It is believed by most investigators that urotropin circulates in the blood in its own form. Casper found free formaldehyde in the blood of a rabbit to which urotropin had been given subcutaneously, but not in the blood of patients taking the drug. Loebisch and Linoissier claim to have detected formaldehyde in the blood after the administration of urotropin. The fact that urotropin is excreted unchanged by the kidneys is evidence against its decomposition in the blood under ordinary circumstances. Perhaps is those cases in which formaldehyde has been found in the blood, it has been liberated under the action of the acid gastric juice and absorbed as such.

The fate of urotropin after it enters the urine is still a subject of contention. Formaldehyde cannot be demonstrated in the urine of all patients taking urotropin, yet clinical experience proves that some antiseptic body is present.

Part of the urotropin excreted by the kidneys is undoubtedly partially or completely decomposed in the urine, if it is acid in reaction, and it is probable that this decomposition occurs, at least in part, in the renal tubules. From the clinical evidence of its action in cases of cystitis with ammoniacal urine, and the well-founded assumption that urotropin is not decomposed in alkaline solutions at the body temperature, the extent of this decomposition before the urine reaches the bladder must be considerable. Cammidge failed to find formaldehyde in the urine of a healthy adult taking 30 grains of urotropin per day, and concluded that the exact chemical nature of the body which acts as a urinary antiseptic is unknown. He believes, however, that acid urines produce partial decomposition of urotropin in the kidneys at which time the antiseptic element is formed, and emphasizes the fact that such decomposition takes place only in the presence of *acid urine*. Hence drugs which diminish the acidity of the urine should not be given in conjunction with urotropin.

Others, however, notably Nicolaier, Loebisch and Casper, contend that free formaldehyde is split off in the urine. Citron, while admitting this, thinks that the formaldehyde immediately

* Read before the Section on General Medicine, New York Academy of Medicine, April 21, 1903.

re-combines with some substance in the urine, probably the sodium salts, and does not exist there as such. Nicolaier has found by *in vitro* experiments that formaldehyde splits off from urotropin in the presence of uric acid, and believes that formaldehyde is liberated in the body in this manner.

We may sum up these opinions as follows: Urotropin is always found in the urine of patients taking it; formaldehyde is found in some cases; and an antiseptic action is almost always manifest.

Whatever may be the manner of its action, urotropin is the most potent and at the same time the most reliable *urinary antiseptic* we possess. Urotropin, however, is not suitable in all cases where urinary antisepsis is desired. Keyes considers that the drug is distinctly irritating to the urinary passages and that in straightforward cases of chronic posterior urethritis and acute cystitis it may do more harm than good. This opinion is based on extensive clinical experience, but is not shared by many who are equally well qualified to speak. Hahn says urotropin is practically useless in bladder cases when the urine is acid in reaction.

The *diuretic action* of urotropin, though marked at times, is not constant. How urotropin acts as a diuretic is not known, but as it rather lowers blood pressure in large doses, it is probable that it acts through local stimulation of the kidney cells.

The action of urotropin as a *solvent of uric acid* and even of uratic calculi has been highly praised, but it has not fulfilled the expectations of its advocates, as the experiments of Casper and Mendelsohn have shown.

Casper claims that urotropin relieves *phosphaturia* in a remarkable manner.

As the literature on the therapeutic actions of urotropin is rather full no further space need be given to it, and we may turn our attention to its toxic actions, using the term to include all untoward effects.

The toxic actions of urotropin, reported to date, as far as I have been able to find after a thorough search of the literature, include:

*a.—Minor Toxic Actions*, which may be grouped under a single heading.

1. *Irritation of the stomach*, as shown by impairment of digestion and slight malnutrition, has been observed with comparative frequency. Dr. James R. Hayden tells me he has seen it several times. Richardson reports one case of nausea and vomiting, which he attributed to the fact that, contrary to his custom, the urotropin was administered on an empty stomach.

2. *Diarrhea and Abdominal Pain.*—Diarrhea has followed the administration of urotropin in a few cases, accompanied in one instance by abdominal pain. Hematuria also occurred in Forbes' case. Drake-Brockman states that when urotropin is used "as a diuretic, it may cause slight purging, particularly if there be enlarged prostate and irritable bladder." Grosglik has seen urotropin cause diarrhea, but fails to state in how many cases. The diarrhea ceased on the discontinuance of the drug.

3. *Irritation of the Skin with a Measles-like Rash.*—Only one case of this has been reported (Cammidge). It occurred during an experiment on a healthy adult taking 10 grains of urotropin three times a day. The iritation began on the fourth day of the experiment as formication, which was most marked at night and in parts pressed on by the clothing. It became more intense each day and on the sixth day a diffuse red rash, somewhat like measles, appeared. Both the irritation and rash disappeared quickly when the urotropin was discontinued.

4. *Headache and Ringing in the Ears.*—Suppan reports that some patients had headache and ringing in the ears, but states that these effects usually diminished when the use of the drug was persisted in.

5. *Irritation of the Kidneys.*—Ordinarily, urotropin causes no irritation of the kidneys, even when they are the seat of previous disease. In fact Nicolaier states that he has seen the disappearance of albumin and casts as well as blood from the urine under the action of urotropin. Yet urotropin undoubtedly has caused renal irritation. Nicolaier succeeded in producing albuminuria in a rabbit after single daily doses of 150 grains of urotropin. Grosglik states that pains in the region of the kidneys occurred in some of his cases (number not stated) after the use of urotropin, and disappeared on withdrawing the drug. Keyes and R. E. Brown have seen renal irritation result from urotropin. Griffith has reported the following case of albuminuria:

Patient, aged twenty-one years, mild typhoid fever. Up and on a fish diet. Taking 10 grains of urotropin three times a day. On the tenth day, was quite ill with backache, swelling of the eyelids and weakness. The urine was almost solid with albumin. The urotropin was immediately discontinued, with the result that the albumin disappeared by the third day. The patient continued well.

The readiest explanation of the irritant action of urotropin on the kidneys is that formaldehyde as it is split off acts as a local irritant in susceptible cases.

*b.—Irritation of the Bladder.*—This manifests itself under two forms, (1) strangury, and (2) cauterization (Keyes, Jr.) of raw surfaces.

1. *Strangury.*—Irritation of the bladder is perhaps more commonly seen than any other toxic effect of urotropin. Nicolaier stated in his original paper that several patients after continued large doses of urotropin complained of burning in the vesical region, generally after micturition, which radiated along the urethra, and was sometimes accompanied by increased frequency of urination. Examination of the urine in these cases showed only a moderate amount of transitional epithelium and no other abnormal constituents. If in spite of these symptoms, the remedy was continued in the same doses, the trouble increased in severity, and occasionally

red blood corpuscles appeared in the sediment. With diminution in the size of the dose or discontinuance of the drug, the irritation disappeared.

Nicolaier also mentions a case of cystitis, probably of several years' duration, with ammoniacal urine and only slight vesical pains, in whom the pains were increased by the administration of 90 grains of urotropin a day. With doses of 7½ to 22 grains per day, the pains were not present, or at most, only transient.

Wider experience with urotropin has shown that vesical irritation, even with proper dilution of the drug, is not an infrequent result of its action. Keyes believes that urotropin is distinctly irritating to the bladder and states that, though this belief is at variance with many authorities, it is founded upon extensive clinical experience. As already said he has found that in straightforward cases of chronic posterior urethritis and acute cystitis, urotropin may do more harm than good.

The vesical irritation may vary from slight increase in the frequency of micturition to intense strangury, accompanied by the presence of blood in the urine. The tendency to vesical irritation is proportional to the size of the dose only in general terms: it appears to be due rather to individual susceptibility. I have seen a single dose of 7½ grains of urotropin, properly diluted, produce such intense strangury that opium and hyoscyamus suppositories had to be given for relief, yet Nicolaier has administered as much as 90 to 150 grains daily without such effects.

It is undoubtedly true that in many instances the vesical irritation has been attributable to the fact that the urotropin has been administered in too concentrated form.

2. *Cauterization of a Raw Surface.*—In this connection an observation made by Keyes, Jr., of an irritant action of urotropin on an operation wound of the bladder is of interest. The observation in brief was as follows:

After suprapubic prostatectomy the lower part of the wound which was left open for drainage and was bathed with urine containing urotropin (5 grains, t. i. d.) became covered with a leathery slough by the second day, and remained in an unhealthy condition until (eighteenth day) the urotropin was discontinued. Afterward the wound healed uneventfully. He has seen a similar reaction in a wound of the scrotum which had been irrigated with formaldehyde. While he believes that this tendency to slough under the action of urotropin is a personal idiosyncrasy, he thinks that the fact should be kept constantly in mind.

Ehrmann has reported a case in which urotropin acted somewhat similarly: Patient, aged twenty-five years, tuberculous infiltration of the prostrate, tuberculous cystitis and ulcers of the urethra. The administration of urotropin was followed by improvement in the condition of the urine, but the patient complained of burning along the urethra which was probably due to the action of urine containing formaldehyde on parts of the urinary passages denuded of epithelium.

*c. Hematuria and Hemoglobinuria.*—As already stated, Nicolaier observed the presence of red blood cells in the urine after large doses of urotropin, especially if the drug was not discontinued or its dose diminished after the occurrence of strangury. In a case of tuberculous cystitis reported by him, urotropin caused the appearance of red blood corpuscles in the urine, but not in sufficient number to give it color. Nicolaier produced hematuria experimentally in dogs with urotropin, but only after the administration of single daily doses of 230 grains.

A careful search of the literature has brought to light *seven cases of hematuria* caused by urotropin, with one doubtful case, as the patient was taking turpentine in addition to urotropin. Hayden, Swinbourne, Johnston and Keyes, Jr., who use the drug extensively, tell me they have never seen it cause hematuria. In a case which has come under my observation there was marked hemoglobinuria in addition to the hematuria, the number of red cells being totally inadequate to account for the amount of hemoglobin.

*Case I.*—Reported by T. J. L. Forbes. Patient aged sixty-two years. Cystitis of ten days' duration. The urine was ammoniacal and contained pus but no blood. Prostate enlarged. Urotropin was given in 10-grain doses thrice daily, dissolved in half a pint of warm water. Two days later the urine was better. On the third day the patient complained of dysuria, burning along the urethra, abdominal pain with diarrhea, and had marked hematuria. The urotropin was immediately discontinued; by the fifth day the blood had disappeared and the urine had become ammoniacal. The urotropin was resumed, but in smaller doses—5 grains t. i. d.—and again, after the third dose, there were strangury and hematuria. Forbes believed that the bladder was the source of the hemorrhage.

*Case II.*—Reported by W. A. Milligan. Girl aged fifteen years; given 5 grains of urotropin three times a day to produce diuresis. After taking the drug for seven days the patient suffered from an uncomfortable sensation in the bladder, accompanied by increased frequency of micturition. Hematuria followed and according to the patient was pronounced. Thinking nothing was wrong, she continued to take the urotropin two days longer, and as her condition became worse sought advice. Examination of the urine showed a large amount of blood. The urotropin was immediately discontinued, with the result that the hematuria ceased and the urine became normal in two days' time.

*Case III.*—Reported by W. Langdon Brown. Patient aged thirty-three years. Typhoid fever. Ailing for some weeks, ill and delirious for four days before admission. Given urotropin, 10 grains three times a day. Two days later complained of pain and dysuria. On the seventh day, blood was present in the last portion of the urine. On the eighth day, blood was seen oozing from

the meatus, and a little more blood was seen the same evening. The urotropin was stopped, and on the ninth day, the dysuria and blood had disappeared.

*Case IV.*—Reported by W. Langdon Brown. Patient aged twenty-four years. Typhoid fever. Ailing for a few weeks. Ill in bed for two days before admission. Given 10 grains of urotropin three times a day. On the sixth day the patient suffered from pain and dysuria. On the seventh day blood with actual clots appeared. The urotropin was stopped. The following day the condition had improved, and soon entirely disappeared.

*Case V.*—Doubtful. Reported by W. Langdon Brown. Details not given. Author simply states that a typhoid fever patient taking urotropin developed hematuria, but that the patient was also taking turpentine, and hence the hematuria cannot be charged entirely to the urotropin.

*Case VI.*—Reported by Alfred Gordon. Patient aged twenty-nine years. Cerebrospinal syphilis with cystitis. Given 5 grains of urotropin three times a day. By the end of a week the pus had diminished in quantity. Four days later, or about the eleventh day, blood appeared with each urination. The urotropin was stopped and the hematuria disappeared. After an interval, urotropin was again given with the same result.

*Case VII.*—Reported by Nicolaier. Patient, a boy aged eleven years. Difficulty in passing urine for six weeks but no pain. At night urine was passed involuntarily. His lungs were unsound and albumin, pus cells and tubercle bacilli were found in the urine. There was pain in the kidney region. He was given 3¾ grains of urotropin twice daily, which he bore well, but without effect on the urine. One year later patient returned for treatment. Urinary organs in same condition. Few red blood cells in the urine, but not enough to color it. Given 3¾ grains of urotropin four times a day. After a week of this treatment there was not only no improvement, but hematuria had occurred. The blood dropped to the minimum when the drug was discontinued. Again the urotropin was given and again the hematuria appeared. The drug was withdrawn and the urine returned to its former condition.

*Case VIII.*—Reported by H. C. J. Biss. Female, thirty-three years old, suffering with typhoid. Bacilluria on fifty-fourth day. Urotropin was given in 10-grain doses thrice daily. Strangury occurred four days later. On the thirteenth day hematuria accompanied the strangury. The urotropin was then discontinued. The strangury disappeared in two and the hematuria in four days.

*Case IX.*—Personal observation. This case possesses unusual interest from two standpoints, the occurrence of cystitis as a complication of pneumonia,* and the development of hematuria and hemoglobinuria within twenty-four hours after the administration of 7½ grains of urotropin. A woman, aged seventy-three years, was taken ill with pneumonia. Seven days later, before the lung had cleared, the patient complained of a burning sensation in the region of the bladder with increased frequency of micturition. This condition had developed without previous catheterization or other interference with the bladder. Examination of the urine showed a few pus cells as the only abnormal feature. The vesical irritation gradually increased in intensity during the next four days in spite of treatment, and during the afternoon of the eleventh day the urine became very cloudy. By the following morning it was ammoniacal. At 10.25 that morning the patient was given 7½ grains of urotropin dissolved in half a pint of water. (The frequent intervals at which the patient was taking nourishment threw the urotropin within an hour after she had had 3 oz. of squeezed beef.)

By two o'clock intense strangury had developed from which she got no relief in spite of the free use of opium and hyoscyamus suppositories, until 7 o'clock. I withheld the urotropin after the first dose but that night ordered another tablet for 7 A.M., without cautioning the nurse not to give it in case the urine became bloody. At 4 A.M. or 17½ hours after the urotropin was given, the urine was deeply blood-stained, and at 7 o'clock as ordered—before my morning visit—the second tablet of urotropin was administered, this time on an empty stomach.

The chief points in the examination of this urine were, its alkaline reaction, dark red color (absorption bands of reduced hemoglobin), heavy cloud and gelatinous sediment, large amount of mucus, pus cells, epithelium (some cells from bladder) and red blood corpuscles.

Though the red blood corpuscles were numerous, their number was not sufficient to account for the amount of hemoglobin present, so that we must recognize the presence of hemoglobinuria as well as hematuria. A careful search was made for blood casts, but none were found.

Irrigation of the bladder was begun the day the hematuria appeared.

The urine possessed the same characters for twenty-four hours, then its color became lighter, and by night was almost free from blood. The next morning (forty-eight hours after the hematuria developed) the condition of the urine was as bad as ever, but the blood disappeared during the day. On the fourth day (counting from the urotropin) there were only a few streaks of blood, caused evidently by the irritation of the catheter used in irrigation.

The urine was now free from blood till the night of the seventh day, when the catheter again apparently brought away a few streaks (urine passed before the irrigation contained none).

Then on the ninth day the hematuria (without hemoglobinuria) developed again, the urine clearing by the night of the tenth day, and on the eleventh day the urine was free from blood. On

* Hare and Dare in their exhaustive study of the Complications of Pneumonia do not mention cystitis.

the twelfth day the hematuria reappeared, became more marked that night, and though varying in amount did not completely disappear till the night of the fifteenth day.

If urotropin is entirely eliminated from the body within a day or two after its administration, then the reappearance of the hematuria on the ninth day and its paroxysmal nature afterward introduce another element into the case which will be discussed later. As neither a bacteriologic nor cystoscopic examination was to be thought of except as a last resort, two important points must remain undetermined—the bacteriological cause of the trouble and the state of the bladder wall.

The urine now remained free from blood for nearly four days and the vesical irritation became much less distressing, yet the evidences of cystitis persisted unabated. The urine was very foul, containing so much mucus that it would block a large catheter, large numbers of pus cells, and so many triple phosphate crystals that small concretions often came away in spite of two thorough irrigations a day.

In view of the condition of the urine and the uncertainty in my mind as to the extent to which the urotropin was implicated, I determined to give the drug another trial. It certainly was indicated. Accordingly I ordered another dose of 7½ grains dissolved in half a pint of water. The drug was given at 5:45 A.M., three-quarters of an hour after milk. Within three hours strangury had developed and in 4¼ hours the hematuria and hemoglobinuria returned. By night the strangury had diminished and the condition of the urine improved. The blood disappeared by morning and there has been no return of it. As I write, six weeks later, the bladder has returned to practically a normal state, only a few pus and epithelial cells remaining.

The reappearance of the strangury, hematuria and hemoglobinuria, after the urine had remained clear for nearly four days, within five hours after the dose of urotropin and their disappearance within twenty-four hours after withdrawal of the drug, seem to justify me in the conclusion that urotropin was the immediate cause of the hematuria and hemoglobinuria.

If this conclusion is warranted, then the condition of the urine during the sixty hours following the first administration of the drug is directly attributable to it. But some other explanation must be offered for the return of the hematuria on the ninth day and its paroxysmal nature for the six succeeding days, because no urotropin had been given. The most plausible assumption is that of ulcer of the bladder wall. There was presumptive evidence of this in the great distress which the irrigations caused and in the fact that several times urine passed but a short time before the passage of the catheter for irrigation would be clear, while that which came away through the catheter would contain blood, particularly toward the end. The diagnosis, of cystitis with ulceration of the bladder wall, while not absolute for lack of a cystoscopic examination, seems justified by the facts.

The hematuria and hemoglobinuria after the first adminstration of urotropin lasted sixty hours, after the second for twenty-four hours. The explanation of this difference lies in the fact that two doses of seven and one-half grains each were given at an interval of about twenty-one hours, on the first occasion. It would be interesting to know to what extent the condition of the bladder wall contributed to the production of the hematuria, or if in this case hematuria would have occurred without a preexisting anatomical change in the bladder wall.

Concerning the source of the blood in hematuria caused by urotropin, Forbes has expressed the opinion that it comes from the bladder and the fact that in one of W. Langdon Brown's cases blood was seen to ooze from the meatus urinarius confirms this opinion. In my own case I was led to the same conclusion.

As in all of the cases of hematuria, strangury has preceded the presence of the blood, this symptom should be looked upon as an indication of danger.

Johnston has observed two cases in which hematuria disappeared while the patients were taking urotropin.

*Case I.*—A girl aged twenty-two years, was taken with characteristic symptoms of catarrhal grip. Hematuria and hemoglobinuria appeared two days later. Blood was present in such quantity that clots formed in the urine on standing. She was given 7½ grains of urotropin three times a day to prevent bladder infection, and the urine cleared absolutely in five days.

*Case II.*—Male, aged thirty years, teamster, was perfectly well previously. Hematuria followed lifting a heavy piece of furniture, and was marked. Given 7½ grains of urotropin three times a day. The hematuria had improved after four days and was gone in a week.

Since the physiologic and therapeutic actions of urotropin are due to the liberation of formaldehyde in the dissociation of the urotropin molecule, re-combinations aside, it will be interesting to inquire to what extent the toxic effects of urotropin have been reproduced by intravenous injections of formaldehyde.

Robert Maguire has performed three remarkable experiments upon himself with formaldehyde. The facts of these experiments will be seen to have important bearings upon the toxic actions of urotropin.

Maguire had his house physician inject 100 cubic centimeters of a 1:2,000 solution of formaldehyde into a vein of his arm. Formaldehyde appeared in the urine in about one hour, the urine became abnormally acid and contained albumin. In another hour the urine had returned to normal.

In this experiment 0.064 grm. of formaldehyde was used, giving approximately 1:100,000 of total blood. A few days later 263 cubic centimeters of a 1:2,000 solution of formaldehyde were

injected into a vein rather quickly. The solution gave out or Maguire would have taken more. "Immediately," he says, "hematuria and hemoglobinuria appeared." An hour later the urine was still more bloody. Then, when passing urine four hours later, he found that small blood clots had formed in the bladder, which were expelled with difficulty. Considerable irritation of the bladder was present. Still later, the urine was of a brownish tint, but contained no ordinary albumin or ordinary blood-coloring matter. (He was unable to collect the urine for a complete examination.) The following day all the urinary changes had disappeared.

The amount of formaldehyde used was 0.168 grm. giving approximately 1:40,000 of total blood.

On still another occasion Maguire took 63 cubic centimeters of a 1:1,000 solution of formaldehyde. The experiment was stopped because of "extreme cramp-like pain and faintness." There was great irritability of the bladder but no urinary change. A mild but troublesome attack of dysentery developed, the intestine pouring forth a great quantity of mucus. Shortly after the injection he suffered from severe bronchial catarrh, in fact from catarrh of nearly all the mucous membranes, as far as could be ascertained, except the stomach. The amount of formaldehyde used was 0.081 grm.

These experiments are suggestive from several standpoints and throw at least some light upon certain hitherto unexplained actions of urotropin. They prove that under certain conditions formaldehyde may cause hematuria and hemoglobinuria, and suggest that when urotropin causes strangury the cause is the liberation of free formaldehyde in the urine. The appearance of the red blood corpuscles in the urine immediately after the injection and the presence of blood clots four hours later seem to implicate both bladder and kidneys in the production of the hematuria and to prove that the immediate cause of the bleeding is a local irritant action of the formaldehyde.

Ewing, Park and Payne have found from experiments on rabbits that intravenous injections of dilute formaldehyde solutions cause destruction of red blood corpuscles. The estimated proportion of formaldehyde in the blood in one of Ewing's rabbits, 1:11,000, was much higher than in Maguire's experiment upon himself, 1:40,000, yet only in Maguire's case did hematuria and hemoglobinuria occur. Nor is any change in the urine recorded in the experiments of Park and Payne.

We find, then, that all the more important toxic actions of urotropin (intestinal irritation, renal irritation, strangury, and hematuria and hemoglobinuria) have been produced by intravenous injections of formaldehyde.

Prof. Witthaus informs me that one gram of urotropin yields, in complete decomposition, 1.2842 grams of formaldehyde. The amount of formaldehyde employed in Maguire's second experiment and which caused such severe toxic symptoms, was 0.168 grm. Here we have further evidence that urotropin when given by mouth is only partially decomposed in the body, and from the presence of urotropin itself in the urine, that this decomposition takes place only, or at least chiefly, after its excretion by the kidneys. In the single case in which hemoglobinuria occurred after administrating urotropin, it must be assumed that the drug was decomposed either in the stomach or in the blood, since the hemoglobinuria cannot be accounted for on any other assumption.

*Conclusions.*—1. That the administration of urotropin may be, but is only rarely, attended by toxic effects.

2. That toxic actions (especially strangury) occur with comparative frequency if the urotropin is not properly diluted.

3. That the development of toxic effects is not always, or necessarily, correlative with the size of the dose of urotropin.

4. That individuals vary greatly in their susceptibility to the action of urotropin.

5. That urotropin has been known to produce the following toxic effects:

A. *Minor Toxic Actions.*—(1) Irritation of the stomach; (2) diarrhea and abdominal pain; (3) measles-like rash; (4) headache and ringing in the ears; (5) renal irritation, sometimes with albuminuria.

B. *Irritation of the Bladder.*—(1) Strangury, the most common of the toxic effects; (2) irritant action on raw surfaces in the urinary passages.

C. *Hematuria and Hemoglobinuria.*—Eight positive cases of hematuria, following the administration of urotropin, and one doubtful case, have been reported. In one case hemoglobinuria was associated with the hematuria.

6. That the more important of these toxic actions have been produced by intravenous injections of formaldehyde.

7. That the toxic actions of urotropin are due either (1) to special susceptibility to the action of formaldehyde or (2) to interference with the usual disposition of formaldehyde in the body, or (3) to the liberation of an unusual quantity of formaldehyde.

8. That the toxic effects of urotropin generally disappear completely within a few days after withdrawal of the drug.

## BIBLIOGRAPHY.

The following bibliographical list contains but a small proportion of authors consulted in the search for the toxic actions of urotropin, and includes only those whose statements and opinions have been quoted:

## OBSERVATIONS ON EIGHTEEN ABDOMINAL SECTIONS, PERFORMED WITHIN THE PAST YEAR, INCLUDING THE SUCCESSFUL REMOVAL OF AN OVARIAN CYSTOMA WEIGHING SEVENTY-TWO POUNDS.*

BY EDWARD N. LIELL, M.D.,
OF JACKSONVILLE, FLA.;
FORMERLY LECTURER ON GYNECOLOGY, NEW YORK POLYCLINIC; VICE-PRESIDENT, FLORIDA STATE MEDICAL ASSOCIATION.

During a period of a little over twelve months I have performed 18 abdominal operations for various conditions existing within the abdominal and pelvic cavity. These were as follows:

Five for ovarian cyst; five for cystic disease of ovary; four for appendicitis; one for intestinal obstruction; one for ruptured tubal pregnancy; two myomectomies for uterine fibroid.

In addition to these I have performed vaginal section twice, once for suppurating pelvic hematocele, and once for pelvic abscess. None of the patients operated upon were from the service of any hospital, some being seen with and operated upon for fellow practitioners. In several of the cases the diagnosis was made by the attending physician before I saw the patient.

I have no wish to take up your time stating the cases in detail, but some of them call for comment at my hands, in that these present some features of interest and demonstrate the value of surgical interference, which is looked upon much more favorably by a discriminating public to-day, the suggestion by the surgeon that an operation is required finding a more ready response from the patient. No surgical procedure, however, should be advised or adopted except there be a reasonable hope that it will result in the cure or marked relief to the patient. Unfortunate results have followed operations performed as a last resort, as well as operations attempted by those whose opportunities have been too limited to fit themselves for the work.

The fascination of abdominal surgery, the brilliant results achieved, and its increasing scope but stimulates our attention to its importance. The incision by McDowell, that marked the birth of successful ovariotomy; the successful operation for vesicovaginal fistula, through the master-hand of Marion Sims, which gave birth to the surgery of diseases of women; and the recognition by Lawson Tait of the true pathology and diagnosis of ovarian and tubal disease and their imperative removal: these are distinctive as well as progressive periods. The perfected work in pelvic surgery to-day, the treatment of inflammatory diseases of the ovaries and tubes, of pelvic hematocele, of fibromyomata, of uterine displacements, these and others lead us to appreciate the difficulties and helplessness of surgeons who have preceded us in this field. The axiom of Lawson Tait "When in doubt, make an exploratory incision" has proved the searchlight in pelvic surgery, and the morbid specimens thus removed gave an impetus to the science of pathology by affording an opportunity for interesting study. As the etiology of pelvic disease has been more closely defined so has the treatment of the various conditions advanced upon a more scientific basis.

The class of cases first to be referred to is that of ovarian cyst. In one of the five patients upon whom I operated the tumor weighed 72 pounds. This patient, aged twenty-seven years, had been married seven years and was sterile. About the time of her marriage she noticed a slight enlargement on the left side of the abdomen, which steadily increased in size, her abdomen being enormously distended at the time she consulted me in November, 1901, she having considerable difficulty in breathing and being obliged to sleep in a semi-reclining position because of abnormal pressure. Examination showed the uterus to be but slightly enlarged and anteverted. I made a diagnosis of ovarian cyst and advised operation, to which she subsequently consented. Upon abdominal section, April, 1902, the diagnosis was verified, when I removed an enormous unilocular cyst of the left ovary, the contents, of a turbid, syrupy consistence, containing varied-sized fat globules, measuring 6¾ gallons and weighing with the removed sac 72 pounds. The shock to the patient in the removal of such an enormous tumor was much less than I anticipated, though this may be accounted for in great part by the fact that I evacuated the contents gradually, twenty-five minutes being taken therefor, preliminary to enucleation of the sac. The adhesions were profuse, numerous bands necessitating ligation with catgut; the pedicle of the tumor or sac was four inches broad, enucleation of which being by what I term an Odd-Fellow's signia chain ligature of heavy twisted silk, followed by a re-enforced double-loop ligature. The walls of the sac varied from one-eighth to one-third of an inch in thickness. As the adipose tissue of the abdomen was 1¼ inches in thickness, the patient having weighed 227 pounds previous to operation, I concluded to suture the peritoneum separately with catgut, using the interrupted Lambert suture; the fascia and muscle were then brought in perfect apposition with heavy catgut, and the remaining wound left to

* Read at the Thirtieth Annual Meeting of the Florida State Medical Association, held at St. Augustine, April 8 and 9, 1903.

close by granulation tissue, with dressings of iodoform gauze, the wound being entirely and firmly closed at the end of six weeks. Time of operation, one hour and twenty minutes; highest temperature, 99½° F., on the third day. The right ovary and tube, apparently normal, were not removed. When last seen by me, five months after operation, the patient was in perfect health, the cicatrix being firm with no tendency to ventral hernia.

The other case in this class which I wish to make mention of was a woman aged sixty-five years, married and also sterile. When referred to me she had just recovered from an attack of traumatic peritonitis, on the left side mainly, and it was at this time that a growth was noticed on the right side by the attending physician, the patient never having been conscious of such until so informed. Upon examination the diagnosis was made of ovarian cyst, mobility being independent of the uterus. An abdominal section showed the tumor to be a right parovarian cyst the size of an ordinary grape fruit, having a twisted pedicle, with profuse adhesions to intestine and omentum, the result of peritonitis previously referred to. After carefully separating the adhesions the sac was unfortunately ruptured in my efforts to enucleate the growth intact; the peritoneal cavity was irrigated with normal salt solution, no drainage, and the abdominal wall sutured through and through with twisted silk. The patient made a gradual but uninterrupted convalescence.

Of the five cases operated upon for cystic disease of the ovaries, but one will claim your attention, it being one associated with complete retroversion of the uterus with adhesions, the left ovary being three times the normal size, the right sclerotic and somewhat atrophied. This patient, aged twenty-eight years, married two years and sterile, gave the usual history of premenstrual pain, backache, with added irritation of the bladder and frequent micturition. After freeing the uterus from its attachments posteriorly, followed by the removal of both ovaries and tubes, I performed a ventrosuspension of the uterus, a portion of each latero-anterior surface of the fundus being sutured loosely with catgut to the peritoneal tissue at the lower angle of the abdominal wound. These combined operations relieved the patient not only of pain but of the bladder distress as well. In this connection I would note that of the nervous disturbances in women a large percentage is the direct result of inflamed or diseased ovaries and tubes. Where the ovary and tube of one side only is involved we conserve the sacrifice of the opposite ovary and tube.

Of the four cases of appendicitis operated upon by me it was my misfortune to lose two. These deaths, however, can not be attributed to the operator, they being operations of emergency,—suppurative and perforative, and which I was called in haste to perform many miles from Jacksonville. Were it a question of a surgeon's percentage mortality and recoveries my better judgment would have dictated not to operate in these cases; it was the desire of the attending physicians and the parents of both patients that I should give the patients the possible chance, which I proceeded to do. In operations of emergency, even though death be invited, one cannot always decline to operate.

In every case of fatal appendicitis there has been a period in which the patient could have been successfully operated upon. There is no other major surgical operation which is so reasonably sure of success, symptomatically as well as surgically, after early operation, and when prompt interference means as much to the patient as in appendicitis. Elevation of temperature, while a necessity to diagnosis, is no indication of the degree or extent of the pathologic process; furthermore, preconceived ideas based upon experience often prove valueless, as a positive opinion prior to operation cannot be given as to location, attachment or condition of an appendix.

Of the two recoveries, in one, a young man aged twenty-eight years, who was operated upon in May last, temperature being 102⅗° F. at the time of operation, the appendix was of a size of one's little finger, acutely congested and in part gangrenous and bordering on perforation; the omentum was very much injected and partly adherent; this was separated and a portion of the adherent omentum removed; the mesentery attachment was firm with a broad base and pedicle, silk being used as ligature. In this instance the pedicle ligature worked up through a narrow sinus and was extracted two weeks subsequent to operation. This case was of rapid development. The second case of recovery was one of interval operation; by that I mean I operated after a second attack, thus precluding a third attack. The appendix in this instance was rather long and adherent to the cecum, which adhesions were carefully separated before ligation.

The two cases in which death occurred are of interest; in one, a girl aged thirteen years, the disease was fulminating in character, of but three days' duration. The appendix was the diameter of one's thumb, gangrenous and having sloughed at its base, with honey-combed pus pockets and adhesions profuse; septic peritonitis was in evidence. A hard, fecal endolith the size of an orange seed was found in the middle third of the appendix, a condition which in the early days of appendicitis had given rise to the theory of orange, lemon or cherry pits as the chief factor in etiology. The other case, a young man aged nineteen years, temperature 103° F. was what I term one of sacculated suppurative appendicitis, an appendiceal abscess with protective adhesions, in which I removed fully a quart of fetid pus, the abscess cavity being drained by means of iodoform gauze strips carried through a small opening left unsutured in the abdominal wound, the sac not being removed. This case is a remarkable instance of appendiceal abscess with protective adhesions, in which sac there was contained fully one quart of fetid pus which had

been forming some days, the first symptom of appendicitis having developed almost three weeks previous to operation. It is of further interest in that it presented conditions similar to those existing in the case of King Edward VII, operated upon less than a year ago, though in my case the patient's vitality was at a low ebb at the time of operation.

In the case of intestinal obstruction, the patient was aged thirty-three years and single. She had been operated upon about eight years ago by Dr. Joseph Price, of Philadelphia, at which operation the tubes and ovaries were removed. About five years ago she began to complain of a sense of discomfort and dull aching in the right iliac region, which had gradually increased in intensity. Three days previous to my seeing her, in consultation with a fellow practitioner in another city, she presented symptoms of intestinal obstruction. Upon examination of the patient I believed the appendix to be also involved, the conclusion being arrived at by the attending physician and myself that the obstruction of the bowel was evidently the result of some adhesion or fibrous band. Immediate operation was advised and accepted. A loop of the ileum, within a foot of the ileocecal junction, was found strangulated and cyanosed by a fibrous band one inch in length and the diameter of a goose quill, running from the stump left of the broad ligament to the middle portion of an elongated appendix, the latter being very much injected and inflamed. The fibrous band was ligated with catgut at the old stump and the appendix, including the band, removed entire. Patient was entirely relieved of all untoward symptoms and made an excellent recovery.

The fifth class of cases, that of tubal pregnancy, I have operated for twice, both successfully, within the past thirteen months; one by abdominal section three weeks previous to the last meeting of this Association at Tampa and which case I reported with specimen, at said meeting. As a coincidence, I operated upon a second case of ruptured tubal pregnancy within a month of the one reported, though I performed a vaginal section in this instance, with equally good result. The condition was one of suppurating pelvic hematocele, the inflammatory retro-uterine pelvic mass being about the size of a large grape fruit. The patient, aged twenty-nine years, had two children, and gave a history of menstrual suppression and complicated pelvic trouble of several months' standing. A free transverse incision in the posterior vaginal wall and evacuation of the contents of the sac—protective adhesions having confined the contents—was followed by packing the cavity with iodoform gauze and subsequent repeated dressings.

Tubal pregnancy is much more frequent than we have been led to suppose. Formad having found it in 35 autopsies in deaths from other causes. The question of recognition and diagnosis previous to rupture, when the opportunity for investigation presents itself, is a leading one and is practicable in a majority of cases. There are a number of instances recorded of recurring tubal pregnancy, and while such may be expected in a considerable proportion of pregnancies that occur subsequent to a tubal pregnancy, I do not believe we are justified in removing the remaining and apparently normal tube and ovary at the primary operation.

The sixth and last class, that of myomectomy for uterine fibroids, I have operated upon two cases. The first, a woman aged thirty-two years, married and sterile, gave a history of severe backache, a sense of weight in the pelvis and a frequent desire to urinate; menstruation regular. Upon examination the uterus was retroflexed, somewhat prolapsed and enlarged to the size of a large orange, the posterior portion being especially developed. A diagnosis of fibroid was made and operation advised and accepted. Abdominal section showed a fibroma the size of a lemon, subperitoneal, having a broad base and springing from the posterior wall of the uterus. Here then was a typical case for the comparatively new operation of myomectomy, of which I took advantage. I made a free perpendicular incision in the posterior wall of the uterus through the peritoneum and the capsule of the fibroid and enucleated or rather shelled out the latter, hemorrhage was controlled by a rubber ligature around the cervix, and a portion of the excess peritoneal tissue was then excised in order that the line of suture, which included a portion of uterine tissue, would coapt the peritoneal edges more closely; medium-sized catgut was the suture material used. Patient made an uneventful recovery.

The second patient upon whom I performed a myomectomy for fibroid had not yet passed the climacteric; she had borne two children and for five months previous to operation had irregular hemorrhages; examination detected a fibroid the size of a large walnut in the anterior wall of the uterus. Upon abdominal section I found that its removal was equally feasible as in the preceding case, and, therefore proceeded to do a myomectomy; being on the anterior wall and thus more readily reached, its removal was not as difficult as the case just referred to.

The operation of myomectomy or fibroid enucleation, whenever possible, should take the place of amputation or total extirpation of the uterus. It is the operation of election in all single and multiple subserous tumors with well-defined borders; but the question can be decided usually only after opening the abdomen.

While the causes of fibroma are as obscure as those of tumors in general, yet from the present state of our knowledge of fibroid development and the pathological changes which take place in such tumors, and the frequently accompanying chronic invalidism or fatal termination, I am convinced that these should warrant surgical interference independent of any absence of symptoms of either pain or hemorrhage. Furthermore, the mortality of a do-nothing treatment is over 30 per cent., as compared with 5 per cent.

through surgical interference by skilled operators, as shown by tables given by Martin, of Berlin, and Noble, of Philadelphia

It has been my good fortune in my abdominal work for many years past, never to have met with an instance of secondary hemorrhage. I have never departed from silk as a ligature, the size of the silk used depending upon the size and thickness of the pedicle; I always make positive that my ligatures are both well-placed and always reinforced. Catgut has always seemed to me treacherous, the main difficulty being in tying it firmly so as not to slip and also its liability to fray.

The best means of prevention of abdominal or ventral hernia are small incisions and accurate coaptation of the various layers of tissue, thus securing firm apposition. In layer or tier suturing, desirable in patients with considerable adipose tissue, catgut and kangaroo tendon, in my opinion, are preferable and meet the indications best, being absorbable.

A point which I desire to emphasize is needless delay in operating as a factor leading to increased mortality. The diagnosis having been made and the necessity for operation having been determined, it is well to obtain the patient's immediate consent thereto and thus avoid the mental worry and excitement postponement may cause the patient.

---

## THE EFFECT OF ERYSIPELAS UPON ATROPHIC RHINITIS; WITH REPORT OF CASE.*

BY LEWIS S. SOMERS, M.D.,
OF PHILADELPHIA.

WHILE the report of a single case of any disease which has been benefited by measures somewhat foreign to those usually found of value, can in itself prove of little service, yet isolated facts present possibilities for future studies on a larger scale and, therefore, the case which forms the subject of this report seems suggestive in the light of the present trend of serotherapeusis.

Atrophic rhinitis accompanied with ozena and not dependent upon disease of the accessory sinuses, implies by the very nature of its pathology, a condition which of necessity is not susceptible to complete structural restoration and it also implies not only the avoidance of the individual so affected by those with whom he comes into contact, but the constant attention to the nasal passages with all the difficulties encountered in the removal of the tenacious and partially dried secretions. While cases of this affection have from time to time been reported as being cured by various local measures, such results are but partial and do not apply to the restoration of the atrophied turbinal tissue, but rather to a clinical disappearance of the subjective symptoms and odor; which is satisfactory to the patient and from the nature of the case is practically all that can be expected.

As is well known there exists a certain antagonism between various diseases, the presence of one affection precluding for a time, at least, the development in the same individual of another, the immunity thus conferred existing for various periods of time; yet to a lesser extent and infrequently, the protective immunity of one disease over another is not only conferred upon the individual, but this power is more largely emphasized by the observation that in certain instances a pre-existing affection may be cured by the development of another disease in the same individual; erysipelas being the type of the disease at times presenting this therapeutic efficiency and the one which has been studied in this connection to the greatest extent, while advantage has been taken of the fact to use the products of the erysipelas organism in the combat against certain malignant changes. The following case is therefore presented because of its peculiar interest, inasmuch as it shows an apparent clinical cure of atrophic rhinitis in which ozena was prominent, and secondly, the manner in which this favorable termination was secured, that is by the influence of a severe attack of facial erysipelas.

W. S., male, aged thirty-eight years, had always been troubled with dryness of the nasal chambers and pharynx as long as he could remember, and especially since his tenth year. No history could be elicited of the usual diseases of childhood, he was abstemious in his habits, presented no evidences of syphilis and except for nasal catarrh in his mother and to some extent among the individuals of her family, the history was negative. His chief complaint was the presence of an intensely fetid nasal odor which at times became so marked as to be commented on by those associated with him, and which at such times prevented him from attending to social duties. In addition to this the nose and nasopharynx would become blocked at least once during the day and especially on arising in the morning, with large greenish crusts which were removed with difficulty and frequently attended with nausea and vomiting. Objectively, the nasal interior was roomy and filled with greenish crusts, emitting to a most marked extent the odor characteristic of ozena. On removal of the crusts the turbinals were pale, atrophic in great part, but the lower on both sides presented a few isolated spots of relatively normal tissue; the pharyngeal wall being visible through both nasal chambers. The nasopharynx was covered with masses of partially dry and offensive mucus, while the pharynx was red, dry and sclerotic. In other words, the case presented the usual picture of atrophic rhinitis without involvment of the sinuses, that is so frequently seen. He had received treatment both by others and myself, but except for the relief obtained by cleansing of the nasal chambers several times daily, other measures such as citric acid, oil of mustard, the tampon with iodine, etc., seemed to have but slight temporary effect, unlike the results usually obtained in the larger number of patients suffering with a similar condition.

On April 18, 1902, he received a slight blow

* Read before the North-Western Medical Society, April 7, 1903.

over the right eye, only sufficient to barely break the skin, and within twenty-four hours erysipelas developed over the bruised parts and rapidly involved the entire face and neck. The features became unrecognizable, abscesses developed on each of the upper and lower lids and a portion of the lateral cervical glands suppurated. The mucous membrane of the nasal interior was also involved, while the pharyngeal mucosa became dry and fissured. The attack of erysipelas ran the usual course, remaining localized to the head, face and nasal chambers, and the patient was free from all symptoms of the disease by May 5. A careful examination of the upper respiratory tract was made a few days later and it was found that the ozena had entirely disappeared, the nasal mucosa was in part covered with but few crusts and easily removed, while the necessity for the frequent removal of the inspissated secretions had entirely disappeared. The lower and middle turbinals on each side were still shrunken, but they presented a more healthy appearance inasmuch as small areas of mucous membrane more nearly approached the normal. The nasopharynx and pharynx still being in part crusted and dry, but in no degree comparable to their former condition. No treatment was advised except occasional cleansing with an alkaline solution, as it was desired, in view of the favorable results produced by the erysipelas, to observe if the changes were permanent in character. At the present time, the nasal mucosa remains somewhat shrunken and atrophic in patches over the turbinals, but is elsewhere apparently normal and the healthy areas are increasing in size; the secretions are practically normal and while there is occasional crusting, it produces no obstruction and absolutely no offensive odor is discernible. The upper pharynx shows in a marked manner the improvement, as it is no longer dry, fissured and covered with adherent secretions, but while the submucous tissue remains atrophied, the epithelium has been fairly well restored and except for a slight degree of dryness due to the diminished secretion, it no longer is the source of the previous annoyance.

Several centuries ago it was noticed that erysipelas would occasionally favorably influence, and in some individuals, cure various pathological changes, but until recent years no advantages were taken of this phenomena, other than it was considered a favorable influence for an individual suffering from some form of malignant growth for instance, to become the subject of an attack of erysipelas, as there was the possibility of the amelioration or cure of the pre-existing disease. At present, numerous investigations have been made upon this influence of erysipelas, and no doubt can exist but that the disease has a distinct influence upon certain affections, although this favorable effect is not constant and does not limit itself to any special class of pathologic changes. Syphilographers, especially, have at various times noted the disappearance of certain of the local manifestations of syphilis when the affected parts were coincidently involved in an erysipelatous infection and convincing evidence from clinical experience has shown that not only has the general course of syphilis been modified, but also that indolent and suppurating buboes, have been favorably influenced.

Of other diseases which erysipelas has ameliorated or cured, there are numerous authentic reports: Powlowsky has seen local anthrax cured under these circumstances; Hebra and others have described the permanent cure of lupus nodules; Terson saw a case of advanced leprosy of the conjunctiva ameliorated, the leprous nodules for a time disappeared entirely; while Hessler reported a case of epilepsy with from 40 to 70 attacks a month, attacked with facial erysipelas and after the acute infection had disappeared, the convulsions practically ceased. It cannot be doubted that erysipelas has caused the permanent disappearance of various cutaneous tumors, carcinoma of the mammary gland, tumors of the lymphatic glands and epitheliomata and, as stated by Coley, this curative action is an established fact and is more powerful in sarcoma than in carcinoma.

While numerous instances of the amelioration of various affections by erysipelas have been recorded, its effect upon atrophic rhinitis has not been observed; a careful search of the literature revealing but two cases, both reported by a single observer—Francesco—and of but recent origin. The first was that of a young girl, with ozena of seven years' duration, which had resisted all treatment. Erysipelas incidentally developed, originating at a point near the nostril and involved the face. After the attack had subsided, the odor and crusts entirely disappeared, the mucosa recovered its normal appearance, and as three years later there had been no relapse, the case undoubtedly could be considered as a complete cure. The second case was that of a young woman with ozena of the left nostril, which had resisted treatment. While nursing a brother with erysipelas of the leg, she developed the disease on the lobule of the left ear, and with the experience gained by the previous case, the author scarified the cheek near the ala nasi in order that the nasal chambers should become involved. The erysipelatous process then affected the entire cheek and nasal chambers, and when the patient recovered there remained no trace of the ozena.

Since Busch, in 1866, observed in a woman with multiple sarcomata, the development of erysipelas following his attempts to remove the growths, with their disappearance as the result of the infection, a new light was shed on the subject, and numerous attempts have since been made to relieve various affections by the inoculation with erysipelas, its prepared streptococci or its serum. In relation to its therapeutic efficiency, the most favorable results have been seen from accidental infection, while next in value is the culture and finally the toxins as experimentally isolated, are lowest in the scale of practical value. The best results in malignant tumors at least are obtained from erysipelas itself, but Emmerich found in animals that the serum had a

restraining influence on tubercular lesions of the eye, and he was able by its use to cure splenic fever and malignant pustule in rabbits.

Of the more striking features presented by this case, the disappearance of the clinical symptoms of the ozena as a direct result of the erysipelas and the efforts at regeneration which have progressed toward a favorable histologic change, seem worthy of careful attention. The latter phenomena showing itself most strikingly by the islets of normal mucosa increasing in size and by the increased vascularity of the nasal interior, with its more normal secretion.

A suggestive thought in this connection is that of the influence exerted upon one bacterium by another; it being well known that in laboratory cultures, the presence of one bacterium will in many instances prevent the growth of another, and in view of the presence of the *Bacillus mucosus* ozena in the nasal chambers in some cases of rhinitis, whether bearing an etiological relationship or not it is impossible at present to say, it may prove of some interest should the bacteriologist determine the degree of antagonism between this bacteria and the organism of erysipelas. While one could hardly suggest that ozena should be treated by streptococcus cultures as a routine measure, yet in a small class of cases in which treatment has failed to control the ozena and in which the patient is obliged to desist from active business or social relations on account of the nasal condition, it would seem that the injection of Coley's fluid, for instance, would possibly be productive of some material benefits. At all events it would seem desirable to note the effect of intercurrent attacks of erysipelas upon a pre-existing atrophic rhinitis, and the careful study of such cases from this aspect may possibly be the means of elucidating some of these complex problems.

## ESOPHAGOSCOPY.*

BY EDWARD A. ARONSON, M.D.,
OF NEW YORK.

Laryngoscopy, oroscopy, cystoscopy and rectoscopy are all recognized aids for diagnostic purposes and it is my object to place the subject of esophagoscopy before you and claim a place for it alongside the above-mentioned clinical aids. If one takes up any book on clinical methods or diagnosis, he will find very little or no space given to this subject. Sahli, in his latest edition, says, "esophagoscopy, by means of the esophagoscope will be a very practical aid to diagnosis, but up to the present time the introduction of the instrument is too burdensome and too severe for the patient."

The idea of examining the esophagus by means of various instruments, originated with Störk in 1866, after laryngoscopy had been completely established. In 1868, Bevan described the use of an instrument for the examination of the esophagus. Waldenberg, in 1870, invented an instrument which came nearer to the modern one; for illumination a lamp, head-mirror and laryngeal-mirror were used. In 1880, MacKenzie began his examinations of the esophagus and in 1881, Mikulicz was the first to devise a long tubular instrument, the one end of which projected out of the oral cavity and thus did away with the use of the laryngeal mirror. He used a small electric lamp attached to a slender rod which ran along the inner side of the tube and illuminated the distant end. By the aid of this light, Mikulicz observed many interesting conditions, both in the normal and pathological esophagus. Leiter made improvements on the principle of the Mikulicz esophagoscope, and von Hacker then began to use it.

Since then, most esophagoscopes have been constructed on the ideas of the last mentioned authors, with but slight modifications. Some clinicians use the Casper electroscope for illumination purposes, that is, the illumination is kept at the upper or outer end of the esophagoscope. Störk modified the Mikulicz instrument by making a flexible end to it of jointed steel rings, which after introduction and with the patient in proper posture, resumes its straight position; there are, however, no advantages in its use. Kelling has also devised such an instrument, which in its entire length is made up of steel joints.

We now come to the modern instruments, from the more simple one of Rosenheim to the most recent one of Glücksmann. Rosenheim devised an instrument which differs slightly from that of von Hacker and that of Mikulicz. I will describe the Rosenheim instrument as follows: it is a smooth metallic tube, 11.5-13 mm. in diameter, and may be of any length between 22 and 50 cm. The distal end is slightly thickened and made dull, and to this end is fixed a soft rubber tip attached to a rod called the mandrin, introduced into the tube; this rubber tip makes the introduction of the instrument less dangerous. When the instrument has been completely introduced, the mandrin with the rubber tip is withdrawn and a Casper electroscope is attached to the outer end of the tube. The eye is placed to this end of the tube and by means of the electrical illumination, the esophagus in part, after sponging away whatever mucus or blood there may be present, is brought under immediate observation. The tube on its outer surface is marked off by a centimeter scale, which enables one to see how far he has entered the esophagus.

Einhorn also devised an esophagoscope with a miniature electric lamp at its lower end; this instrument he exhibited before the Medical Association of Greater New York in December, 1901. Schreiber invented a more complicated tube,

* Read before the American Medical Club of Berlin, Germany, Feb. 28, 1903.

which has a second much thinner tube attached, through which the mucus can be withdrawn and thus do away with sponging. Glücksmann, early this year, demonstrated an instrument on the Rosenheim principle, but which, in addition, had a rubber ring at its lower end that could be inflated from the upper part; this allowed a greater separation of the esophageal walls and thus afforded a larger field for observation. He has the lamp at the upper or outer end of the tube, objecting to the light at the lower end because if the lamp becomes covered with pus or blood the illumination is obscured.

The position of the patient is a very important consideration for the introduction of the instrument and each clinician has his favorite position and favorite instrument. Einhorn used his own instrument with the patient in the sitting posture; Störk, with the old instrument, always had the patient in the sitting posture; Mikulicz places his patients on the right or left side; von Hacker allows his patients the dorsal position; Boas, the sitting or horizontal posture, and Rosenheim always preferably uses the horizontal position.

Before introducing this instrument, the patient's general condition must be examined and all constricting clothes removed. If there are no contra-indications, such as I shall mention further on, to its introduction, then the whole posterior portion of the oral cavity is well anesthetized, with a 10- to 20-per-cent. cocaine solution or a 3-per-cent. eucaine solution; formerly, a hypodermic injection of morphine preceded the introduction of the instrument. Most clinicians precede the use of the esophagoscope by the introduction of a sound and Kraus lays especial emphasis on this point.

Mikulicz in his early work with the esophagoscope, described the esophagus as having three different motions, all visible by means of this instrument: Respiratory—during expiration an approximation of the walls and vice versa in inspiration; pulsatory—seen at the bifurcation of the trachea and extending downward, because of the close proximity to the heart; peristaltic, which is less frequently seen. The normal mucosa of the esophagus is very pale red in color and very smooth. Under pathological conditions, the surface alters its appearance and color and the vessel injection, especially in inflammatory conditions, is very easily recognized.

Although the instrument affords such advantages in diagnosis, its introduction in some cases is attended by some disadvantages, among which may be mentioned, (1) patients unable to open the mouth widely and the presence of the incisor teeth; (2) hypersecretion of mucus; (3) entrance of some secretion into the larynx, followed by cough; (4) vomiting; (5) diminished flexibility of the cervical vertebræ; (6) acutely convexed tracheal cartilages; (7) unrest of the patient.

The length of time necessary for the examination of a patient with the esophagoscope depends upon its effect on the patient and the local condition; in fact, an examination need never last more than three minutes, and, if necessary, may be repeated several times, always allowing a few days between each examination. It need hardly be necessary for me to say that the instrument should be immediately withdrawn in case there is a marked hemorrhage. It is hardly possible to make such an examination without assistance, as some one must support the head of the patient. Esophagoscopy is attended with but one serious danger and that is, perforation; this, fortunately, has been a very infrequent occurrence. The indications for esophagoscopy are: (1) To note the site and character of foreign objects within the esophagus; (2) to recognize local lesions, such as erosions, ulcers, etc.; (3) to note the character of an obstruction, if one is present; (4) to recognize new growths, benign or malignant; (5) to recognize a diverticulum, though this is not easy; (6) for differential diagnosis between organic and functional conditions of the esophagus; (7) last, but most important, for therapy, such as the extraction of foreign objects, local treatment of ulcers, erosions, etc.

Among contra-indications may be mentioned, nervous patients; debility; patients with short thick necks; marked emphysema and dyspnea; myocarditis and uncompensated heart lesions; aneurism and arteriosclerosis; kyphoscoliosis; liver cirrhosis with tendency to hemorrhages; acute inflammation of the esophagus.

When anyone for the first time is about to see an esophagoscopy performed, he always asks himself, Can such a barbarous looking instrument be easily passed and what is the effect on the patient? No matter what the posture of the patient is, whether sitting, on the side or horizontal or on the back, in every case the head is thrown as far backward as possible, which makes the esophagus more or less straight and favors the passage of the tube. The effect on the patient varies with the individual; some patients submit very quietly and suffer no very unpleasant results, and others struggle, become cyanotic, breathe laboriously, and require more or less moral anesthesia to quiet them. The after-effects may be some slight intrathoracic pain, which gradually and rapidly passes away. Many a patient will readily endure considerable inconvenience, pain and marked cyanosis if the foreign body be withdrawn from the esophagus through the tube; the physician, on the other hand, will feel more than gratified, when he notes the diminished respiratory motion of the esophagus wall, due to its infiltration, the presence of a little pale prominence with or without a bleeding point, that he has made diagnosis of carcinoma.

Esophagoscopy to-day is practised most frequently in Germany in but two clinics, at that of Mikulicz, in Breslau, and at that of Rosenheim, in Berlin, where I have had the opportunity of examining a large number of cases during the past months and to form an opinion as to the advantages of esophagoscopy. To get simply an idea of what really has been done by esophagoscopy, one need but read the excellent monograph of Gottstein on the subject.

It would not be quite fair for me to say that this method of examination has found universal satisfaction and while it has its ardent admirers, it also has others such as Ewald, Boas, and Kuttner, who hesitate longer in its employment for diagnosis and say the latter should be made without the instrument and without subjecting the patient to it; which, after all, are but insufficient arguments against its use. Kraus says, "Esophagoscopy without doubt is of great diagnostic value, more valuable perhaps in the hands of the surgeon because of its therapeutic indications." Mikulicz in the preface to Gottstein's monograph says, "The esophagoscope not only allowed us to view well-known clinical pictures better, but has directly brought before our eyes conditions which heretofore were unknown or but poorly recognized and falsely diagnosed. Up to the present time, the one control for a clinical diagnosis was the post-mortem examination but all cases do not come to autopsy and esophagoscopy offers another control."

Formerly a skeptic, I have been completely won over to the use of this instrument and there is no doubt in my mind, that the esophagoscope in the hands of a careful observer who knows how to correctly interpret what he sees, is a most valuable aid to diagnosis.

## INDICATIONS AND COUNTER-INDICATIONS FOR PROSTATECTOMY.*

BY L. BAZET, M.D.,
OF SAN FRANCISCO, CAL.

Not long ago, the medical profession thought that in perineal prostatectomy, a radical method had been found for the cure of hypertrophy of the prostate; many operations were performed the world over, each operator recorded his cases, and medical newspapers were full of this literature. Now it seems that after the enthusiasm of the first moment, more reflection is exercised, and we do not hear of so many prostatectomies performed. Discrimination has been made. Experience has sanctioned operation in only those cases that give assurances of a probable good result. To facilitate the selection of these operable cases, the writer of this paper submits to you what he considers the indications and counter-indications for prostatectomy.

In the pathogeny of the accidents of prostatism, many factors come into play. In stating that the hypertrophied prostate plays the most important rôle, I must submit that there are individuals who have for many years a very large prostate without being troubled. Notwithstanding this contradictory fact, the prostate is often the first pathological factor. Under the influence of its hypertrophy, the bladder is disturbed in its function, the urine does not flow through the urethra with the same freedom, and then begins the vesical evolution of perturbation, which is first acute, then intermittent, then chronic retention. Vesical contractility will become weaker from day to day and at the end of a period, varying generally from eight to ten years, the patient will arrive at the condition of complete and definite retention. At that time the catheter life and its attendant miseries begins and ultimately conduces to the death of the patient. During all this time the necessity of catheterization exposes the patient to the accidents of infection.

Prostatism is made of all these combined, associated and blended elements, and when the responsibility of treatment has to be assumed for a prostatic patient, it is necessary to make a complete examination and to establish a precise diagnosis. The observations must be related in detail, the group of symptoms disassociated, the succession of accidents established, and those relating to each organ carefully analyzed. Without these precautions, there is risk of performing an unjustifiable and useless operation, or, at all events, of failing to obtain the hoped-for result.

To make a complete diagnosis of prostatism, it is necessary to analyze the individual, the apparatus, and the organ. Concerning the individual, that is, the heart, the lungs, the arteries, etc., there is here nothing special to be said. As to the urinary apparatus, the kidneys above all are to be examined. The polyuria, the turbid urines, the great deposits, the vague symptoms of Brightism, all the signs of these should be searched. They have a great prognostic value, but their research does not offer any special particularity. With the prostatic, it is the examination of the organ that most interests us, and by organ, I mean the prostate and the bladder. It is to that examination that we must bring great precision, because upon it depends the selection of the operation to be performed.

For the examination of the prostate, many means of unequal value can be utilized. First, the rectal touch: it must be made with an empty bladder, otherwise the prostates, spread by the vesical extension, all appear increased in size.

* Read before the California State Medical Society, April, 1903.

The rectal finger shows the volume of the prostate, its length, its width, its firmness, its consistency. Notwithstanding that these informations are very vague: there are some prostates with rectal evolution that are not large. They are felt by the rectal touch. There are others with vesical evolution that are large and are not felt by the rectal touch. Besides, the rectal touch does not give sufficient information concerning the volume of the prostate. It is only an indication, but, if we combine the abdominal palpation with the rectal touch, it will be easy to gain the conception of an interposed volume, more or less great, depending upon the size of the prostate. Each lobe is to be palpated successively and its relative volume appreciated. However, this is possible only with lean individuals; with corpulent prostatics whom we frequently see, we must employ other methods.

It is then that catheterization intervenes to give us information of the highest precision. The olivary explorator and the bi-coudee sound give us positive data on the volume of the prostate. They make us know the existence of a greater or less prominence on the posterior wall: they show sometimes by the stop they undergo at this level that there is a cul-de-sac of depression with a bar above, but over all they show, by the depth to which they penetrate what is the length of the prostate, and the length of the prostate is in direct ratio to its volume: the more it increases, the more it lengthens. Its superior face is pushed toward the abdomen by the hypertrophy, and the length of the prostatic urethra, which in the normal state is 27 millimeters, reaches a length of 4, 5, 6, and even 7 centimeters. Consequently, to draw the urine off, the sound must penetrate that depth, and an experienced eye can judge of the volume of the prostate by the depth to which the sound has to penetrate.

The metallic explorator confirms these data in two ways: by the depth it attains, it shows the length of the prostatic urethra and besides, by lowering the handle, the elevation of the neck of the bladder is ascertained. The more voluminous the prostate the more will the neck of the bladder be elevated. This is a general law from which the prostate cannot escape. Placed at the inferior part of the pelvic cavity, the prostate cannot enlarge downwards on account of the ischio-pubic rami. Upwards, on the contrary, and there only, it is free. Hence, when the hypertrophy takes place, the prostate rises more or less towards the umbilicus and carries with it the vesical neck, consequently the vesical neck will be pushed upward directly as the prostate is enlarged. But, when the neck of the bladder rises, the bas-fond becomes depressed and the depression of the bas-fond is in proportion to the degree of the hypertrophy. Now, then, this depth of the bas-fond will be shown to us by the metallic explorator.

When the metallic explorator is introduced, if with it you can execute a complete circle of the neck it is because the prostatic pouch exists. In addition to this, by exploring to the right and to the left of the neck, you determine to what extent the right and left lobes of the prostate project into the bladder and, owing to a median obstacle, you can discover the existence of a senile or pedunculated lobe. Thus a series of precious notes are furnished by the intervention of only an instrument commonly used in the search for vesical calculi.

We have another means of determining the intravesical projection of the prostate, *i.e.*, cystoscopy. The cystoscope confirms the data established by the means I have already mentioned. Depth of the bas-fond, median or lateral projections, these conditions are again demonstrated by the cystoscope.

These are the means that permit us to define the exact state of the hypertrophied prostate. Before making a decision, it is necessary to know and appreciate the condition of the vesical muscle. The study of the urinary residuum gives us the nature of its contractility. When the bladder empties itself completely, it is because its contractility is intact; when it empties itself partially, it is because it is already in a state of inefficiency; but when it does not empty itself at all, when the retention is complete, it must not be concluded that the contractility is completely lost: on the contrary, even in these cases, it is rare that the vesical contractility is entirely abolished. It appears that even in complete and chronic retention, the vesical muscle aided by the catheter, has more vitality than in the chronic and incomplete retentions where the patient, neglectful of the catheter, aids less willingly the contractility of the vesical muscle. When the bladder is filled with water and the catheter remains in place, we can judge of the vesical contractility by the intensity of the stream of the liquid column. A manometer is not necessary, as this simple exploration is sufficient. When all these facts are known, it is possible, I think, to weigh with certainty the indications and contra-indications for the treatment.

The indications for prostatectomy are based upon conditions that vary according as the patient labors under the first, second, or third period of prostatism.

In the first period, when only dysuria and nocturnal frequency exist, prostatectomy ought to be postponed. At that time the operation would be somewhat extreme, and I do not see any trouble that may arise by waiting until the period of more serious complications. I see, on the contrary, the advantages of this prudent expectation. But when we find acute retention, which is the first indication of the failure of the vesical muscle, then the question of the operation presents itself again, and this time the operation appears to me to be perfectly indicated if the prostate is large. With a large prostate, congestive attacks will surely return, the retention that has begun will be more pronounced. If it be true that all methods for relief have, in this condition, given extraordinary success, perineal prostatectomy can-

not be inferior to any. The operation reaches the obstacle, which is the prostate; it alone removes that compression made by the lateral lobes upon the lumen of the urethra. Consequently the bladder, freed from this initial primary obstacle, has no more reason to be subsequently disturbed nor its muscular function further weakened. Results will some day show that the patients who have been a long time under observation and subjected to operation at this initial period, have been definitely cured. But, if I reason thus for a large prostate, I will be more circumspect regarding a gland of small volume. Notwithstanding the acute accidents, if the prostate is small, we can wait, and I believe it is better to await under a prudent and vigilant supervision, the manifestation of more serious difficulties.

When the patient has arrived, after a more or less prolonged period of miseries, at the stage of chronic and complete retention, prostatectomy will almost always be indicated. It is then that it will give its best results. Although the vesical contractility appears lessened and even abolished, and although the patient is unable to expel even a few drops of urine, the prostatectomy, by removing the obstacle will permit these patients to urinate spontaneously and sometimes even to empty their bladders. In these cases the obstacle whether it be large or small is the important causative element. If the indication for prostatectomy is indisputable at this period for a large prostate, it is equally so for a small prostate if vesical sclerosis has not been known to be the primary factor in the process. The diagnosis of these cases is, moreover, very difficult to make; and I believe that the doubt ought to be on the side of the operation. I may say willingly that at this stage the operation meets only counter-indications which further on I will mention.

At last the patient reaches the period of incomplete and chronic retention. He has a residue of three to six ounces; he uses the catheter two or three times every twenty-four hours. Should we operate under these conditions? Yes, if the prostate is large. The operation is justifiable because there is chance of improvement, but we must be wisely conservative, because it is these bladders, sclerosed by cystitis, and whose diminished power is imperfectly supplemented by the catheter, that furnish the majority of failures in prostatectomy. Before the operation, the residue was three ounces—it remains the same after. Before the operation the catheter was used three times a day—after, it is necessary to use it the same number of times. The patient has lost his prostate and his condition has not been improved. On these patients I consider the indication of an operation only when there is a large prostate. I attach a great importance to the volume because with the marked enlargement we have the best chance to obtain a good result.

Another indication for prostatectomy in these patients is shown by the presence of calculi which notwithstanding previous lithotrities, continue to recur with the same disheartening persistence. With these patients the prostate is the indirect cause of the relapse. That organ, by elevating the neck of the bladder, forces the depression of the bas-fond and induces calculi to lodge there: that organ, by forcing the retention invites the agglutination of the infected residue, and the formation of calculous concretions. Hence, instead of crushing through the urethra, a calculus where the conditions of production are not modified, I think it more surgical to reach the bladder by the new perineal operation, to remove the prostate and afterwards the foreign body, thus at the same time disposing of the calculus and the condition determining its formation.

But prostatectomy has also its counter-indications, and it is not a paradox to say that, in determining the course of treatment, counter-indications more than indications have to be borne in mind. The consideration of a slight operation on an aged, fatigued person, with all his organs and apparatus impaired, may find in the state of the individual, elements of the highest gravity. Age constitutes the first counter-indication. Beyond seventy-two years, chances of success of operation diminish considerably, and as prolonged life cannot be expected at that age, benefits of the operation are proportionately decreased.

Infection is another factor that pleads against the operation. Here, however, we have to understand each other. The infection is more or less constant with the prostatic, but it can be vesical and remain chronic. But, when it is accompanied by acute congestion and fever, and at the same time there exist chronic lesions of sclerosis and renal infection, the operation presents dangers that ought to defer it to another epoch, and oftentimes postpone it indefinitely.

---

## MORAL INSANITY OR DEGENERACY.

BY F. H. STEPHENSON, M.D.,

OF SYRACUSE, N. Y.;

NEUROLOGIST AND ALIENIST TO SYRACUSE HOSPITAL FOR WOMEN AND CHILDREN; THE SYRACUSE FREE DISPENSARY; THE ONONDAGA COUNTY AND ST. VINCENT'S ORPHANAGES; MEMBER OF NEW YORK STATE SOCIETY; PRESIDENT ONONDAGA COUNTY MEDICAL SOCIETY; CENTRAL NEW YORK MEDICAL ASSOCIATION; SYRACUSE ACADEMY, ETC.

It is agreed among modern writers and observers along psychological and neurological lines that there exists in mankind marked mental disorder with great moral disturbance, yet with the intellect fairly developed and often unaffected or brilliant.

The description of this form of degeneracy is given thus: "A person, who may be educated, cultivated, have a good memory, do many kinds of work well, may even be a genius, but is strongly emotional, unstable, lacking in judgment and reason. Precocity or disequilibration being often marked in some of these patients, the phenomenal mimics, mathematicians and child pianists often come under this heading. In others, the ethical feelings are changed: they lack self-control, giving way to sprees, immorality and other excesses.

and we hear of them periodically taking the gold-cure or recruiting in sanitariums and other health resorts. Often the animal propensities override the intellectual power, as eroticism and sexual perverts, they step mentally and morally over the border line of recognized decency and sanity and then they pass to the criminal or imbecile class, to which they are closely allied. Examples of this type are brought to our notice constantly, either in our professional, business or social relations, or through the daily press.

It is encouraging that these degenerates are being more and more recognized and studied and will receive greater consideration and sympathy as time goes on, and the general public becomes enlightened through our instrumentality, as students and observers, and as our conclusions are given to scientific bodies, to clubs, to the press, and on the witness stand, where we are liable to find ourselves at any time, endeavoring to protect the degenerate from the punishment which should be meted out only to the criminal. This latter class should be looked at from the standpoint of its nervous organization, as usually unstable, and quite prone to develop suddenly mental diseases. In some of these cases anatomical stigmata are well marked, viz.: the ill-shapen and prominent ears, cranial deformity or asymmetry, lanky figure, gothic or flat, broad palative arch, widely separated and irregular teeth; anomalies of the skin, genitalia, etc. In others, the physiological stigmata may be present, consisting of anomalies of the motor and sensory functions of speech, appetite, motion, gait and sexual derangement. Nutritive and circulatory disturbances are frequently observed, also vasomotor symptoms. The psychic disturbances of degeneracy consist of insanity, idiocy, imbecility, neurasthenia, prostitutions, the criminal class, hysterias, epileptics, feeble-mindedness, precocity, eccentricity, moral delinquency sexual perversion and those with poverty of ideas. These people have little self-control over their emotions; they are lacking in reason and judgment and are so sensitive and suspicious that they cannot adapt themselves to their families or employers, their circumstances or surroundings. They are erratic, impulsive, easily moved to tears, fearless or timid, and eccentric, but especially are they lacking in mental balance, that quality which man must possess to a great degree to make a success in life, and to go safely through its trials and vicissitudes. When young and protected by their family or guardians, many of these patients exhibit only a deficiency in moral sense. They may be capable of receiving an education, culture or acquiring a trade; but with the strain and trials of later life their moral nature shows its weakness, if not a state of depravity. Their emotions may become depressed or exalted and they become so agitated that they commit suicide or homicide, their emotional explosions, like those of epilepsy, often bring relief, and they relapse into their normal condition.

Dana says about two per cent. of normal men have the stigmata of degeneration, but man is not considered a degenerate unless several of these deformities are manifest.

According to law they are conscious of right and wrong, and thus they are held legally responsible. Medical men, who study these degenerates, recognize their inability to control their strongly perverted emotions, or the temporary manias or melancholias, which are easily developed in such neurotic soil. These patients are accomplices or perpetrators of sin and crime, but they should be understood and dealt with from their proper standpoint, and they and their families saved from the disgrace which so often befalls them. They may have been considered odd or eccentric, but not until they have committed some criminal or immoral act, or present symptoms of acutely ingrafted insanity, do their friends think of their having always been a little insane, especially at periods, resulting from various exciting causes, as grief, worry, insomnia, excesses, illnesses, or physical debility. The patient then comes under our care and study and we recognize a degenerative psychosis with a latent acute insanity. These cases of degeneracy vary greatly, presenting every shade or mental blemish from morbid ideas, manners and customs to the criminal class and idiocy. But the variety which I wish especially to dwell upon is the one often met with and which frequently puzzles mankind. The one which can be managed with the greatest difficulty and which receives the greatest injustice.

A man of this class was recently tried in the Onondaga County Court for murder. As a child, we learn, he was bright and enjoyed study, but was shy, fond of being along, reading 'way into the night, sleeping but little, was self-willed, uncontrollable, and having constant altercations with his teachers and family. At eighteen years of age he became melancholic and attempted suicide, but failed in the attempt. For the next eighteen years he lived in thirty-six cities, in Europe and America, working for a large number of employers; in fact, constantly vacillating from place to place and from city to city. Few of his reasons for these frequent changes being sufficient, according to the opinion of a man of average thrift, reason and judgment. During this latter period of eighteen years he has twice attempted suicide, while having recurrent attacks of depression. The history of his manners, customs, habits and ideas, as elicited from himself, his relations, his fellow-workmen and employers, shows he was erratic, quick-tempered, easily influenced, unstable, sensitive and suspicious; he entertained socialistic views of life and considered suicide right, if one were unhappy or made a failure in life. He has a good memory and is fond of our best literature; in fact, is educated and intelligent in many ways beyond the average workman. Another peculiarity is that he should fit himself for such a position as a dyer and cleaner of clothing, when educational advantages were offered and urged upon him, and his family were educated people who held and still do hold good social and busi-

ness positions and relations. These tendencies all suggest a perverted, unbalanced and unstable mental condition. Heredity is a potent factor in this class of cases, the family taint being of course greater the larger the number of ancestors and relations afflicted with nervous and mental diseases, as the various neuroses, epilepsy, consanguinity, alcoholism, drug habits, and the various insanities. Such an inheritance is bound to afflict some of its posterity or relations with degeneracy, if nothing more serious. The man referred to comes from a family of neurotics. His mother is eccentric, his sister a paranoiac, an aunt is a meloncholiac, and an uncle and cousin both suicided while suffering from the latter disease. Another cousin is a feeble-minded epileptic. His other brothers and sisters are thus far free from mental disease, while he, poor fellow, has been a "ne'er do well" throughout his life and will continue in this condition, as it is incurable, unless he drifts into some more serious mental disease, which very often develops from this primary condition of degeneracy.

It is important that this condition be recognized in early childhood, and early training, discipline and example exert a beneficial influence. The precocious child should not have especial attention given to his one-sided talent. He should be developed along the line of his *general* ability. Especially should all young children who are self-willed be taught obedience and to think before they act. These points are as necessary to their success in all departments of life, business or social, as the culture, education and business training which we parents and educators are so desirous they shall obtain. Self-poise and self-control are of great advantage throughout life, and very much of this must be cultivated and developed in the home, and especially is this training due to the child who shows a nervous, excitable temperament or one who comes from neurotic ancestry.

My closing wish and thought is that we study more and more these degenerates, educate the public regarding them, and then protect ourselves from their uncertain, emotional movements, and endeavor to protect these unfortunates themselves from the special trials which so easily cause them to lose mental equilibrium, when they are liable to commit some rash deed for which they are not mentally accountable, but for which our laws hold them responsible, unless they show other evidences of insanity which are so marked that a layman can easily recognize them. Then, if they escape the criminal's chair, they only escape to go to the hospital for the criminally insane. Is it not our duty as physicians and observers to educate mankind in general regarding the dangers and expectations from heredity and the lack of self-control throughout life?

The degenerate must be considered solely upon the mental, moral and physical stigmata which brand him as an abnormal or atypical man, and prevent him from exerting himself to the highest limit commensurate with his skill and development.

# MEDICAL PROGRESS.

## MEDICINE.

**Meningitis Without Anatomical Lesion.**—It sometimes happens that patients die very acutely with all the symptoms of a severe meningitis and yet only a slight exudate and perhaps a moderate degree of swelling and hyperemia of the brain is found post mortem to account for the condition. The case of Birnbaum (Münch. med. Woch., July 21, 1903) is peculiar, however, in that the patient was ill for fifteen weeks and that absolutely nothing was found post mortem in the meninges. Bacteriological examination, however, revealed the presence of meningococcus, and the cerebrospinal fluid withdrawn during life showed a slight coagulum, which always is suspicious. The case must therefore be looked upon as one of meningeal sepsis without anatomical lesion. The cause was probably a gum-boil which had been incised with extraction of the diseased tooth, two days before the acute onset of the illness.

**Sepsis Caused by the Diphtheria Bacillus.**—Diphtheria is a disease which leads to intoxication rather than to infection and there are only one or two cases on record where the germ was really found circulating in the blood. The case of Roosen-Runge (Münch. med. Woch., July 21, 1903) is of exceptional interest since the patient originally suffered from another disease. He came to the hospital with a consolidation on one side followed by an empyema in which pneumococci occurred in pure culture. After resection of a rib, the temperature dropped and the patient seemed to be convalescing, until six days after the operation, when the exudate became hemorrhagic in character and fluid appeared on the opposite side with renewed rise of temperature. The course of the disease was now steadily downward, with high fever and dyspnea. The bacilli grown from the blood had all the characters of diphtheria bacilli except that they were not pathogenic to animals. This does not, however, prevent the author from pronouncing the case as one of diphtheria sepsis, probably taking its origin from the wound in the pleura.

**General Sepsis Caused by the Pneumobacillus.**—A patient apparently suffering from sepsis with marked involvement of the lung was observed by F. Jenssen (Münch. med. Woch., July 21, 1903.) Other prominent symptoms were an enlarged and tender spleen, albuminuria, very rapid pulse and remittent temperature with only a single chill. From ten cubic centimeters of blood taken from the cephalic vein, abundant growths of the Friedländer bacillus were obtained. The patient died after a week and at autopsy there were found pleuritis, multiple foci of consolidation in both lungs, abscess in the kidneys, abscess of the liver perforating into the free peritoneum, diffuse purulent peritonitis, splenic tumor and cloudy swelling of the heart, liver and kidney. The portal of entry could not be ascertained, the infection might have taken place from the lungs or tonsils though the patient's history seems to point to a gastro-intestinal origin. The Friedländer bacillus has been found in purulent inflammations of almost all organs of the body, yet cases of general infection are rare and reports on positive blood-cultures are still more infrequent in literature.

## SURGERY.

**A New Incision for Resection of the Appendix.**—The new incision of E. Beer (Centralbl. f. Chirurg., July 25, 1903) is a modification of the one recommended by Gerster, and does not injure the posterior sheath of the rectus. The skin is incised directly above a line which connects the navel with the middle of Poupart's ligament, about 1 to 2 centimeters mesially from the

outer edge of the right rectus; in length the incision should not be more than 3 to 4 centimeters. The rectus is then pushed inward, when the semilunar fold of Douglas and the inferior epigastric artery come to view. Now the peritoneal cavity is opened directly beneath the semilunar fold and external to the inferior epigastric artery. The risk of a subsequent hernia is thus reduced to a minimum. Should the opening prove too small, it is still possible to open the posterior sheath of the rectus. The peritoneum is finally closed by means of a continuous catgut suture, the anterior sheath with chromicized catgut or silk, and the skin with silk or adhesive plaster.

## NEUROLOGY.

**The Pathogenesis of Acute Psychoses.**—This has long remained one of the unsolved problems of psychiatry and none of the numerous theories advanced have stood the test of experimental trials. The view which has lately met with the most support is that these phenomena depend on delicate chemical changes in the cortical cells, which occur without the production of any morphological alterations in the cells themselves. In this way the theory of a circulating toxin in the blood has gradually gained credence. Experimental proof of this theory has been sought by H. Berger (Berlin. klin. Woch., July 27, 1903). The first of these trials were performed by the author on himself. He injected at intervals serum, blood and cerebrospinal fluid from a patient suffering from acute dementia with hallucinations, without the least effect. This seems to show that the toxin, if present, must already be firmly united with the cerebral cells before the acute symptoms appear. In the belief that the toxin may have been found during the prodromal stage, the author also injected subcutaneously blood from a patient who was developing symptoms during her puerperium, which later turned out to be a dementia precox. No effect was seen, but blood taken from the same patient four weeks later, during a fresh attack, and injected, was shortly followed by vertigo, and later by cardiac palpitation, cerebral pressure, and a marked feeling of fear. All these symtoms subsided on the following day. A similar experiment with the blood taken from a more advanced case in a condition of stupor at the time, was also followed by results which were much more marked and severe and did not subside for a week. The experiments were then continued on animals and a basis secured for further investigation in regard to the changes which specific toxins contained in the circulating blood may cause in the central nervous system. The details are not suitable for a brief abstract. They consist mainly of observations made with the serum secured from the goat which had been made neurotoxic for dogs, by the continued subcutaneous injection of triturated cerebrum from the brains of dogs. Intracerebral injections of this goat serum in dogs was followed by well-marked pathological changes in the pyramidal cells of the cerebral cortex and later on a large aggregation of leucocytes around these degenerated cells. Similar pathological conditions have been found in patients afflicted with acute psychoses and also in other cerebral diseases, but the author is not as yet prepared to draw final conclusions until further proof has been secured.

## PHYSIOLOGY.

**Rapidity of Growth and Length of Life.**—That the span of life of the mammalia is related to the rapidity of growth, was first pointed out by Buffon and later by Flourens, according to G. v. Bunge (Pflüger's Archiv, Vol. 95, Nos. 11 and 12). They expressed this relationship in a numerical ration, Flourens finding this to be 5, although Buffon thought it was 6 or 7. That is, the number of years it takes to reach adult life, multiplied by 5 would give the duration of life. These observers found the age of maximum growth to be the period at which the epiphyses and diaphyses of the long bones unite. The author, in the course of an investigation on the relationship between the composition of milk and rapidity of growths in the various mammalia, had the opportunity of determining the time it takes the animal to double its birth-weight. The results were tabulated in a series as follows, the numbers referring to days: man, 180; horse, 60; ox, 47; sheep, 15; hog, 14; cat, 9½; dog, 9. This order is exactly the same as that given by Flourens for the period of attaining maturity, tabulated in years, as follows: man, 20; horse, 5; ox, 4; sheep, —; hog, —; cat, 1½; dog, 2. The average duration of life, as given by this author, in years, is as follows: man, 90 to 100; horse, 25; ox, 15 to 20; sheep, —; hog, —; cat, 9 to 10; dog, 10 to 12. From the last two series it appears that the factor 5 of Flourens is not exactly correct. In the determination of the average duration of life there must of course be excluded all these cases in which life is cut short or shortened by accident or disease. To the author it appears that there must be some other functional relationship between the two variables, length of life and period of growth, than the mere numerical relationship, and that even this numerical law might be deduced from some other more general law. At any rate the author is convinced that there is a law of relationship between period of growth and length of life and that the exact determination of this law would be of eminent interest.

**The Coagulability of the Blood of Asphyxia.**—Carbon dioxide does not exert in vitro, according to M. Carrara (Archives Italiennes de Biologie, June 10, 1903), any anticoagulating action upon the blood of asphyxiated rabbits or dogs, but seems to favor coagulation. In fact the blood of such animals coagulates in the test-tube more rapidly than normal blood, which phenomenon is all the more marked the longer the asphyxia has lasted. This accelerated coagulability is to be attributed to the large amount of Ca-ion rendered active by the very conditions of asphyxia (formation of bicarbonates). The osmotic pressure of the blood increases during this condition: but slightly, when it is caused by the sudden or gradual occlusion of the trachea, and markedly when it is produced by $CO_2$ and respiration in confined air.

## HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

**Pathology of Beginning Prostatic Hypertrophy.**—Considerable confusion reigns as to the real pathological changes which underlie hypertrophy of the prostate. In order to observe these in their incipiency, A. Rothschild (Virchow's Archiv, Vol. 173, No. 1) carefully sectioned thirty glands from patients thirty to fifty years old, not suffering from acute infections or constitutional disease or of inflammatory affection of the genito-urinary tract. He found the following changes: (1) Glandular tissue. The glands were dilated and their walls less convoluted. Pathological contents—chiefly pus cells and desquamated epithelial cells, with detritus and amylaceous bodies—were found in nearly all and where the lumen was filled, the epithelial lining was converted into a single layer of cubical or flat cells. (2) Connective tissue. Foci of small, round cells in a process of cell division were frequently encountered in the stroma; their number and location varied considerably, but they were rather frequently found encircling a pathologically altered gland. The blood-vessels and muscle-fibers did not participate in the changes. The lesions of prostatic hypertrophy must thus be classified under chronic inflammation. It is probable that the newly-formed connective tissue com-

presses the gland, but still more so their excretory ducts, so that a stasis and secondary dilation takes place, to which the greater part of the increase in size must be attributed.

**Pupillary Changes after Death.**—The development of rigor mortis follows a certain definite law. Three to six hours after death it affects the neck muscles and then descends to the trunk, arms and legs. After three to four days it disappears in the same order. The heart is involved somewhat earlier than the other muscles. Observations on smooth muscle-fibers are very scant, so that A. Placzek (Virchow's Archiv, Vol. 173, No. 1) made a systematic study of the size of the pupils at various times after death to ascertain if the muscles of the iris follow the general law. Cats were selected, since their prominent iris permits of very accurate measurement. In the first two hours after death, the pupils begin to contract; this goes on until, after six to twenty-four hours, only a narrow slit remains. After twenty-four to forty-eight hours relaxation is again complete and no further excursions are then noticed. There may be individual variations; thus the process need not be synchronous on both eyes of the same animal; the secondary dilatation may be interrupted for a short time by a secondary contraction or the secondary dilatation need not occur at all. The pupil varies much in shape when completely contracted: it frequently is very irregular in outline. In man, rigor mortis of the iris begins in the second half of the day of death or in the first half of the following day, hence is independent of the contractions of the skeletal muscles. Differences on both eyes are also observed very frequently. To explain the contraction it must be assumed that the tonus of the dilator pupillæ is lost much sooner than that of the constrictor pupillæ. The author then examined a number of pupils that were altered in size by drugs shortly before death. Eserin injected subcutaneously was followed by miosis; shortly before death the pupils dilated and after death behaved as stated above. Applied locally there was contraction followed by maximum dilatation in the death agony; the post-mortal changes were the same as before. Exactly the same phenomena were observed after morphine injections and after division of the sympathetic nerve. The post-mortal variations in size were not affected by mydriatics instilled before death any more than by miotics; the pupils did not dilate until just before death and then contracted and dilated as before. When a drug which acts directly upon the muscles of the iris (adrenalin) was employed, the dilatation persisted much longer after death and was followed by only a slight contraction.

**The Relation of Blood Sera to Strychnine Poisoning.**—The success which has attended the efforts to immunize individuals with respect to certain pathogenic agents, has, according to D. Lo Monaco (Archives Italiennes de Biologie, June 10, 1903), inspired many investigators to discover methods of immunizing animals against not only organic but also inorganic poisons. These researches take their point of departure from two facts, namely: the pharmacological experience that all organisms do not react with the same intensity toward certain toxic agents, certain animals having a natural immunity toward particular poisons; and the possibility that animals are capable of acquiring toleration for otherwise deadly quantities of alkaloids or metallic salts, *e.g.*, arsenic eaters, opium fiends, etc. Ehrlich, by the gradually increased and prolonged administration of abrin (a deadly poison contained in jequirity) and ricin, succeeded in immunizing animals against otherwise fatal doses of these poisons, and demonstrated, moreover, that the serum of these animals, when injected into others, transmitted to them this same immunity. Rummo was able to habituate guinea pigs to very large doses of strychnine, and found that the animals thus treated possessed a marked resistance to infection with otherwise fatal cultures of tetanus bacilli. Both Giacosa and Robecchi obtained negative results in the effort to fortify against fatal doses of strychnine, rats, rabbits and guinea-pigs, by means of injections of the blood serum of the hen, an animal strongly tolerant to this drug. Although curare, ether, chloroform, chloral, paraldehyde, the bromides, etc., have been used in strychnine poisoning, none of these drugs can be recognized as an antidote. It is of peculiar interest that Lusini was able to protect rabbits against the minimum fatal doses of strychnine (.6 mg. per kg.) by means of injections of antitetanic serum, administerd before or after the injection of the toxic dose. Centanni and Bruschettini obtained the same results with polyvaccin. The author, inspired by the success of the above investigators, conducted a research with the object of determining whether rabbits may be partially immunized against strychnine poisoning by means of single or repeated injections of the blood sera of herbivorous animals, themselves not specially tolerant of strychnine. He was successful. The blood serum of the horse, and to a more uniform degree, that of the cow, after four or five injections into the rabbit enables this animal to tolerate the minimum fatal dose. The convulsive stage occurs, but it apppears late, is short and is not followed by marked exhaustion. If the prophylactic treatment is continued for about twelve days, the resistance to poisoning becomes more marked. By using the blood of the immunized rabbit and injecting its serum into another rabbit on successive days, the author was able, although in only one instance, to transfer this immunity. He also succeeded in augmenting the resistance of rabbits to strychnine by means of repeated doses of the antitoxins of tetanus, bubonic plague, and, best of all, of diphtheria. He believes that the natural resistance of an animal to this drug has no influence on the antitoxic value of its serum. The fact that a homogeneous serum (that of another rabbit) has no action, as is also the case with the serum of the hen, while the serum of the horse or the cow produced good results, leads the author to infer that the antistrychnic action depends upon the power which the above sera possess, of producing in the animal treated, anti-bodies or antitoxins capable of fixing a certain number of the strychnine molecules. The antistrychnic efficiency of the various antitoxic sera, would seem to depend upon the fact that besides their predominant specific action, they have secondary actions, the side-chains of Ehrlich that are produced in cells sensitive to a certain poison, having either in their greater part a specific action and to a less extent secondary actions, or having this property, namely, that their specificity does not exclude the possibility that they are able to act against other forms of virus, in the absence of the one for which they have been elaborated. In view of the success obtained with the diphtheria antitoxin, the author suggests that it might receive some practical application clinically in the treatment of strychnine poisoning.

**The Communicability of Bubonic Plague to and of Bats.**—Many species of animals have already been investigated with reference to their susceptibility to this disease, according to B. Gosio (Archives Italiennes de Biologie, June 10, 1903). Rats, mice and pigs are spontaneously infected. Experimentally the disease has been communicated also to the muskrat, guinea pig, rabbit, monkey, cat, hen, sparrow and fly. Pigeons are rendered susceptible during the period of fasting, and lizards and snakes by raising their temperature. Immune are the dog, cow, hedgehog and frog. During

the light epidemic of the pest at Naples, the author had occasion to investigate the locality in which the epidemic had its origin, and found it infested not only with rats, but also with a large number of bats. He discovered experimentally that these animals contract the plague and succumb to it in a relatively short time, even after the subcutaneous injection of very small doses. All the internal organs are infected with the specific germs, which are again normally virulent to the rat and guinea pig. Characteristic is the marked splenitis. The parasites of the bat which has been killed by the disease may be infected with the germs, and thus, in all probability, transmit them to the ordinary channels of contagion. The remarkable number of different parasites, the special means of locomotion possessed by the bat and its extreme susceptibility, all give it an importance as a carrier of the bubonic plague.

## HYGIENE.

**Purification and Sterilization of Water.**—As a measure of safety, G. Mellère (Trib. Med., July 18, 1903) holds that all water for domestic use should be sterilized; and that the process of purification should not be confined to drinking water, but should extend to water used in washing vegetables and for other domestic purposes. Naturally the simplest measure consists in boiling, but chemical sterilization may be resorted to if desired; and for this purpose the author suggests peroxide of hydrogen in the proportion of 5 c.c. to the liter. Used in this proportion, it also serves to preserve uncooked milk forty-eight hours in the height of summer; and such treatment of milk in nowise alters digestible or nutritious qualities. The permanganates, in the proportion of 1 to 5 c.c. to the liter, are also serviceable in polluted water; the persistence of a rose color at the end of five hours indicating that the reagent is surely in excess. This excess should be destroyed by addition of a small amount of peroxide. Should purification with peroxide be used as described, the excess of that substance should be neutralized by addition of permanganate sufficient to produce a faint rose tinge; this in turn being caused to disappear by a trace of peroxide. Iodide of potassium, or better, tincture of iodine, may also be used for the sterilization of water; four drops of the latter in a carafe of water sufficing to render that liquid safe for drinking purposes within a half hour. The slight trace of iodine is not prejudicial to health and is neutralized by the food taken.

**Dissemination of Typhoid by Butter.**—This question has been made the subject of practical experiments by C. Bruck (Deut. med. Woch., No. 26, 1903). In these tests water was used to wash out the vessels in which the cream was kept, which had been contaminated by rinsing out in it a cloth slightly soiled with typhoid stools. Butter made from this cream developed colonies the first day, although the stool used for this purpose contained only about sixteen colonies to the plate. The author is inclined to believe that the bacilli are apt to be more numerous in butter than in a like amount of milk or cream. Living bacilli were found in the butter as late as the twenty-seventh day. The greatest increase in numbers occurred during the first few days.

## EYE, EAR, NOSE, AND THROAT.

**Persistent Intubation of the Larynx.**—Chronic post-diphtheritic laryngeal stenoses causing persistent intubation of the larynx are so infrequent that they have not received the attention which this serious condition deserves and the causes have not been fully appreciated. H. W. E. Berg (Med. Rec., Aug. 1, 1903) divides these cases into the following groups: (1) Cases in which the original conditions necessitating intubation persist beyond the usual length of time; (2) cases in which conditions have arisen during or subsequent to the original intubation and which may be due to (*a*) lesions caused by the injurious effect of the intubation tube upon the structures of the glottis, larynx or trachea; or (*b*) may be due to traumatism produced by the operator during intubation or extubation; (3) cases due to the paralysis of the vocal cords, either temporary or persistent. The conditions mentioned in the first group are simply of prolonged inflammatory lesions and might more properly be called protracted cases. In the second group, however, are cases which are the direct result of the insertion or the presence of the tube itself. Although the tube has been such a life-saving device, we should not forget that it is still a foreign body and that its presence in the larynx for any great length of time cannot help but cause some injury. Since the tube is in constant movement during its presence in the larynx, moving with each swallow, cry or even respiration of the patient, it is natural to suppose that unless it is of the proper shape and size serious lesions within the larynx are bound to occur. Decubitus sores, as such injuries are called, are, therefore, rather frequent and are usually situated (1) on the anterior wall of the trachea below the cricoid, due to pressure of the lower end of the tube; (2) above the cricoid over the lateral and anterior surface of the larynx, due to pressure of the retention swell, or (3) on the under surface of the epiglottis, due to pressure against the head of the tube. By far the most important of these is the decubitus above the cricoid laterally and in front, for here is the entrance on both sides of the recurrent laryngeal nerve, the motor nerve of the larynx, and it is urged that it is the pressure paralysis of this nerve which gives rise to the third group of cases, characterized by repeated coughing up of the tubes. Most of these injuries are due to the use of unskilful modifications of the O'Dwyer tube by operators who seem to forget the principles upon which the O'Dwyer tube is constructed. Such cases of decubitus may result in various degrees of stenosis, reincubation oftentimes simply aggravating the condition of the decubitus and finally resulting in permanent intubation to maintain an open passage. When the vocal cords are paralyzed as a result of pressure as described above the tube loses one of its most important means of retention, for the cords do not form a constriction above the retention swell. Thus it becomes very difficult to secure a tube in such a larynx, and it is believed that many of the very annoying and dangerous cases of frequent spontaneous extubations are due to this cause. The prevention of all these complications depends upon careful and skilful work, and an early appreciation of the development of such lesions.

## OBSTETRICS AND GYNECOLOGY.

**Cæsarian Section in Placenta Previa.**—It is impossible to fix upon any definite treatment for all cases of placenta previa, for they differ so much both in regard to the position of the placenta itself and also in regard to the variety of conditions in which the mother may be found. H. D. Fry (Maryland Med. Jour., July, 1903) holds that each case must be handled on its own merits. The tampon and leaving delivery is the best method in one class of cases; the forceps are best in another; podalic version in another; the combined external and internal versions in another, and, perhaps, Cæsarian section in still another. Modern methods have given valuable accessories to success. (1) The recognition of the importance of emptying the uterus in every case as soon as the diagnosis can be made; (2) asepsis has eliminated one great source of fatality; (3) the adoption of bipolar version, and (4) slow extraction of the infant has done much to lower maternal if not

fetal mortality. If the best method is adopted in each case the mortality should be from three to five per cent. Should so serious an operation, therefore, be adopted in a condition with no greater mortality than this? The mortality from Cæsarian section has also been greatly reduced by modern methods and the decision in regard to its use in placenta previa must rest upon the selection of the operation to meet certain combinations of conditions. If the position of the placenta is only partial insertion over the os and the cervix is soft and dilatable it is undoubtedly best to deliver by the natural passages. If, however, the woman is in good condition and is not exhausted by prolonged labor and hemorrhage, if the placenta is implanted centrally, or nearly so, and the cervix is undilated and undilatable, as is frequently found in primiparæ, Cæsarian section, when performed under the best conditions, is not only justifiable but undoubtedly gives the least mortality to the mother and greatly lessens the dangers to the child.

**Ovarian Transplantation and Reconstruction of Fallopian Tubes.**—The very annoying symptoms which sometimes arise from a double ovariotomy necessitated by a diseased condition of those organs frequently need serious attention and the fact that the menstrual function has permanently been stopped is sufficient reason to materially disorder, if not destroy, the subsequent happiness of some women's lives. F. H. MARTIN (Chicago Med. Rec., July, 1903) has encountered two such cases and has attempted to alleviate their symptoms by transplanting pieces of normal ovarian tissue from healthy women in whom other operations were being done, and to whom the loss of a portion of their ovaries was either necessary or at least not objectionable. He gives the details of the operations by which new Fallopian tubes were constructed by suturing the mucous membrane of the uterus to the peritoneum and leaving in a drain which was removed per vaginam after a week or ten days, and also the methods by which the ovarian tissue, carefully preserved in salt solution for the few minutes between the two operations, was sutured into the broad ligaments near the opening of the new tubes. In both of these cases there has been a resumption of many of the symptoms which usually accompany the monthly periods and also a gradually increasing mucous discharge at that time. The time which has elapsed (about eight months) has, however, not yet been sufficient to draw exact conclusions from these cases. Experiments upon lower animals have proved that similar operations may be so successful that conception may subsequently occur.

**Physicotherapy and Gynecology.**—Having used this method of treatment for the reduction or cure of fibroids of the uterus and for the prevention of neoplasms, J. RIVIÈRE (Gaz. de Gyn., July 1, 1903) arrives at the following conclusions as to its efficacy: (1) Ordinarily physicotherapy assists in the recrudescence of fibroids without using exclusively electrolysis, which, other things being equal, should not exceed in strength a current equivalent to 50 milliampères; (2) hydroelectric baths are recommended, with friction to stimulate the skin, remove the dead epidermis, also that the germs may be thus removed, and to assist in the removal of effete matters and organic poisons, and to help the general nutrition of the body. Carbondioxide baths are to be recommended, which, bringing the blood to the skin, stop the flow from the fibromatous uterus, and stimulate and re-establish the general equilibrium of the organic functions. The faradic currents of high frequency, mono- or bipolar vibratory massage are equally of powerful assistance in the treatment of fibromata, as is the continuous current. (3) The treatment by physical and electrical agents, the latter in particular, reduces the pain and metrorrhagia, brings about a return of general and local nutrition and produces a localized anemia and general purification. It is then an etiological medication, rational and scientific to the highest degree, and remarkable in that it is harmless and wards off the performance and necessity for an operation more or less grave. (4) Physicotherapy presents the evolution of benign tumors into carcinomata, principally in women suffering with arthritic diatheses, in whom also carcinomata constitutes a diathesis of the third decade. (5) Acting at the time to bring about epithelial hyperplasia and thickening ureterial involvements, nephritis and other complications; not finding surgery a supplanter of electrotherapy, either aggressive or destructive. Such then are the principal rules of treatment which, in the hands of the careful specialist, furnish a means to a double end and thereby are in truth an undeniable practical progress in the proper direction.

## THERAPEUTICS.

**Value of Iodipin.**—Now that several years have passed since iodipin has been introduced, H. WINTERNITZ (Münch. med. Woch., July 21, 1903) feels himself justified to pass a definite opinion as to its value. Its external application is to be condemned, for even if vigorously rubbed into the skin day after day, no iodine will appear in the urine. The rectal administration, too, is little satisfactory, for only 10 per cent. are absorbed into the system. The addition of pancreatic gland to the enemata somewhat increases the amount taken up, yet this method of giving the drug is very inaccurate. For internal use the 10-per-cent., and for subcutaneous the 25-per-cent. preparation, is used. Iodipin is not acted upon by the saliva or the gastric juice, even where pathological conditions of the stomach are present, nor does any absorption take place from the gastric mucous membrane. An absorption into the lymph-channels finally occurs from the intestines; the greater part of the drug is taken up unchanged and only a small precentage is split up owing to the alkaline reaction of the intestinal contents. In the blood, iodipin circulates in small amounts and in finest subdivision, and free iodine is constantly split off, to unite with the alkali salts present. As soon as this occurs, iodine can be detected in the urine and saliva. The time which elapses from the ingestion of 1½ to 5 grams of iodipin up to the detection of iodine in the saliva is generally only ten to forty-five minutes where the stomach functionates properly. It requires four to six days till 10 grams of iodipin are eliminated, while the same amount of potassium iodide is already excreted in two to three days. The fat, which is not at once utilized by the body, is stored up chiefly in the muscles, liver, bone-marrow and subcutaneous tissue. The slow assimilation explains why intoxication is not likely to occur. The amount of drug lost through the feces is very small; in one case where the feces were analyzed for many days it only amounted to 4 per cent. It also appears in the milk, both as such and as alkali iodine. Turning now to the subcutaneous administration, it was found that after long-continued use, iodine could still be found in the urine 402 days after the last dose was given. Here also the various internal organs and the blood give positive iodine reactions. Massage, bodily exercise and baths will invariably hasten absorption and excretion. It follows from all this, that iodipin is indicated where a prolonged effect is desired, especially since loss of weight and cachexia do not develop. In bronchial asthma, luetic endarteritis and lead colic much more can be accomplished than with the iodides.

# The Medical News.

*A WEEKLY JOURNAL*

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

## HYPNOTISM IN INCURABLE ORGANIC DISEASE.

There is a considerable number of physicians, among whom not a few neurologists, in whose minds the practice of hypnotism is, for some reason or other, connected with quackery, and thus relegated to the class of questionable remedial means. The disrepute in which this frequently very efficient therapeutic agency is held, is entirely undeserved, for though by no means a panacea for every ill that flesh is heir to, it is undoubtedly of great utility in a certain class of cases in which its employment seems to be indicated.

That hypnotism has been of undoubted value in a great many functional disorders not even its most pronounced opponents will deny. Its use, however, in organic affections of the nervous system, though of rather recent date, already shows some interesting results which will undoubtedly attract the attention of the fair-minded and unprejudiced. Those of us who, whether in the clinic or in private offices, were compelled to confess our utter helplessness, in the face of organic diseases, to even alleviate to any extent the sufferings of the unfortunate patients, will be interested to know that in some of these cases hypnotism has brought about a degree of improvement and comparative freedom from distressing symptoms for an appreciable length of time.

Dr. Pevnitzy (*Roussky Vrach*, No. 26, 1903) describes a few of such cases, as observed by him in Bechterew's neurological clinic. In one of the two cases of syringomyelia of four years' duration, which did not respond to any extent to prolonged routine treatment with electricity, medicated baths, massage, strychnine, etc., a three months' course of hypnotism seems to have done the patient a great deal of good, inasmuch as his mental state, formerly markedly hypochondriacal and tinged with suicidal tendencies, became very hopeful; he enjoys good sleep, is able to swallow better than before, while his sensibility to pain and his temperature sense are gradually returning. This improvement, the author is quite sure, can only be ascribed to the employment of hypnotism in the case. In another patient, with transverse meningomyelitis, improvement, thanks to the addition of hypnotism to other treatment, was evidenced by comparative freedom in walking (on crutches), and a feeling of strength in the lower extremities, whereas formerly she walked with very great difficulty. In a tabetic, although the pains and gastric crisis were not markedly influenced by hypnotization, the author succeeded in improving his gait (comparative freedom in stepping over a polished floor as well as in climbing upstairs), and his general condition. Even in a desperate case of syphilitic meningomyelitis hypnotism brought about, temporarily of course, a condition of comparative quietude, and turned a quarrelsome, unbearable patient into one who became grateful and obliging. To be sure, the very great majority of these patients recognize but too clearly the serious nature of their condition, and are intensely interested in anything that carries with it some hope of relieving their suffering. They readily lend their credence to any promise on the part of the physician, and thus become easily suggestible, which fact is of great importance in obtaining favorable results from hypnotism.

## SUBCUTANEOUS INJECTIONS FOR SYPHILIS.

The discussion on the subject of the treatment of syphilis by subcutaneous injections of mercury, at the last meeting of the American Medical Association at New Orleans, brought out the fact that in recent years many more specialists in venereal diseases are employing this treatment than formerly. There seems no doubt in the minds of many men of large experience in the treatment of

syphilis that in certain fulminant cases of the disease a more certain and more rapid effect can be obtained by injections of mercury than by any other means. In visceral involvement, and especially when there are threatening symptoms of syphilis of the nervous system, these authorities prefer the hypodermic method, and the results appear to justify their conclusions in the matter. There are certain dangers, as for instance that of embolism, but it is now generally agreed that, even according to the most unfavorable statistics, this is extremely rare, occurring not more than once in about 3,000 cases. Recent clinical experience shows this accident to have been exaggerated and that occasional symptoms supposed to be due to embolus are really the result of the syphilitic process or of some intercurrent event which symptomatically suggests an embolic process in lungs or brain.

In a very large number of these cases it can readily be understood that coincidental pathological conditions will apparently point to some injury to the nervous system. Dr. Heidingsfeld's case in which, within a short time after an injection, a man developed paralysis of the muscles supplied by the facial nerve and seemed, when first seen, to be suffering from an embolus of the face area in the cortex, proved on more careful study to be simply a case of Bell's palsy. Undoubtedly some of the ill repute of mercurial injections is due to errors of this kind and it should not be forgotten that usually when mercurial injections are employed, symptoms of syphilitic invasion of the nerve centers are already present.

Recently Professor Jullien, of Paris, whose large experience with subcutaneous injections of mercury extends over a quarter of a century, and gives him a right to be heard with attention on this subject, insisted that far from being less prone to give mercury by injection, he employs it with increasing frequency, though by no means does he consider it suitable for all cases. His experience at the hospital Saint-Lazare, which is the lock hospital and prison for women in Paris, and in which all the prostitutes suffering from venereal diseases are confined during the infectious period of their disorders, makes his opinion of great practical value. Neither among these patients nor in his private practice, where he uses the injections whenever they seem advisable absolutely without any sense of insecurity has he met any untoward results.

His favorite materials for injection are the insoluble preparations, especially calomel and gray oil. Calomel is used in doses of about five centigrams for patients whose weight does not exceed 120 pounds, up to ten centigrams for patients who weigh 200 pounds or over. Injections are made every eight days until four injections have been taken and then the intervals are lengthened two days each time until about twenty days is reached as the period when usually the injections are repeated thereafter only about once a month. The technic, however, in this matter is eminently individual, and depends in a large degree on the way the patient reacts to the injection.

Professor Jullien has found the salicylate of mercury well borne and not at all likely to produce either severe stomatitis, pain or the nodular swellings that are sources of so much discomfort to patients when other mercurial preparations are given. Its action is slow but sure. Injections are given usually twice a week, each injection consisting of about six centigrams for an individual of average weight. Professor Jullien insists on the dosage of mercury being adapted to the size as well as the idiosyncrasy of the individual and considers that the salicylate of mercury is very effective in maintaining a moderate mercurialization over a long period.

There are certain advantages in the use of injections that cannot be ignored. Not infrequently has it been found that obstinate and unsightly symptoms of syphilis, which would yield to no other treatment, have yielded almost at once after mercurial injections were begun. The same good results have followed injections for peculiar nervous symptoms, especially those of generalized conditions evidently dependent on the affection of a number of blood-vessels in the central nervous system which have failed to be relieved by even a lengthy inunction cure. It is evident then that every practitioner who has a number of syphilitic patients in his clientele should be ready to give mercurial injections and should know the technic and something definite of the various preparations that have been recommended by specialists in this matter. Whether injections ever accomplish what has been claimed by some enthusiastic advocates of this method of treatment, namely an abortion of syphilis in an early stage, remains very doubtful. Certainly there are patients with many symptoms of syphilis present in whom the use of a few injections of mercury, repeated at longer intervals for a time, has been followed not only by the immediate disappearance of all luetic manifestations, but has put the patient in a condition where no other signs of syph-

ilis have ever appeared. The method has now been before the profession for nearly thirty years, so that such claims can be substantiated by clinical experience of a character to command respectful attention.

### UNSANITARY MILK RECEPTACLES.

Our attention has recently been called to an article written for a dairy paper by Professor W. W. Hall, of Cornell, setting forth the miserable condition in which empty milk cans are found when returned for refilling. With all the safeguards we now have for the protection of the public against harmful and inferior milk it is a trifle humiliating to find this very public acting so carelessly and unconcernedly in a matter of such vital importance to general health. Professor Hall is inspector in a factory where 30,000 pounds of milk are shipped every day to various cities in the State of New York, and he reports that a majority of the bottles returned are in a state too filthy to bear mention, and that the men who are accustomed to handling milk daily can scarcely endure the horrible stench coming from these receptacles.

It seems strange that in an enlightened country like ours, where the people are taught, through the newspapers and otherwise, the great value and necessity of preventing disease by prophylactic measures, that such abject and wholly unpardonable laxity should exist. It is certainly a small enough thing to do when a bottle is emptied to allow hot water to flow into it from the faucet over a kitchen sink and to pour it out again. This is about all that is necessary to clear the bottle of a culture medium in which nearly every kind of bacteria grows in tremendous multiplicity; yet human perversity is such that a like task proves too great for the tired kitchen maid, hence the result.

Professor Hall says: "I made a careful inspection of the cans, after the scrubbing process had been completed and they had been thoroughly treated with live steam, but the foul odor was still there. The dairy farmer is guilty of enough, the factory manager is far from perfection along this line, but no such abuse of milk or milk utensils ever existed at the farm or at the factory as these cans are receiving every day during this extreme hot weather, when the most careful and painstaking methods are necessary."

Yet reprehensible as this practice is, we can scarcely hope for an ultimate change at the hands of servants who constitute for the most part the offending class. The labor problem is already grown too complex to make this element an integral factor in its further development and solution, and we must turn, therefore, to some other way out of the difficulty. Best of all remedies, if it were possible, is the providing of a receptacle efficient enough, yet so cheap that it might be thrown away after emptying, or, better still, which might be burnt in the kitchen fire.

This, however, is not at hand, and until it is we shall have to resort to law. But, on the contrary, legal restriction on milk dealers is becoming so severe that many find it difficult to continue business with any profit. Be this as it may, a well-devised law, compelling the daily collection of milk receptacles from house to house, and a specification of the most effective means of cleansing the bottles and cans, would do much toward an amelioration of the present dangerous conditions.

We can only hope that the New York authorities will take the initiative in this matter.

## ECHOES AND NEWS.

### NEW YORK.

**An Undesirable Patient.**—Leo, one of the lions in New York Central Park, recently consulted an oculist, somewhat unwillingly, and his actions caused the specialist to decide that an operation "will not be necessary." Leo is suffering from a cataract in his right eye. Dr. W. R. Gilfillan said that the operation was not likely to be a success, and that with his left eye the beast could easily find his way about.

**New Women's Hospital.**—Work will soon be begun on the new Women's Hospital, in One Hundred and Tenth street, near Amsterdam avenue. The building is to replace the institution now at Lexington avenue and Fiftieth street. It is to be six stories in height, with basement and attic, and will cost $610,000. In equipment the new hospital will be one of the most complete institutions of the kind in the country. The first floor will have a lecture hall and chapel, the second and third floors will be devoted to private wards, and the fourth floor and the wings will have endowed beds. On the floor above will be a ward for critical cases, and the top floor will be the living place for physicians and hospital attachés.

### PHILADELPHIA.

**Radical Measures to Stamp Out Rabies.**—The State Live Stock Sanitary Board, because of evidence of rabies now existing among the dogs of Columbia County, has decided that all dogs in the county must be quarantined for 90 days. The death of the animal and a fine of from $10 to $100 is the penalty for violating the order.

**Increase in Typhoid and Smallpox.**—For the week ending August 22 there were 118 cases of typhoid fever as compared with 91 of the previous week. The new cases are distributed over all parts of the city, including those wards supplied with filtered water. Twenty cases of smallpox were reported, an increase of four. Director Martin, after a thorough study of typhoid fever conditions in the city is convinced

that from 25 to 35 per cent. of the cases are due to milk instead of water. A directory of milkmen and of establishments at which milk is sold is in preparation and whenever a new case of typhoid fever is reported the milk supply of the house will be traced and examined.

**Typhoid Fever in Schuylkill County.**—Typhoid fever is epidemic in Schuylkill, the disease having broken out at Ashland, Pinegrove, Pottsville, and several other places. The Pottsville Hospital is treating seven cases and there have been a score of deaths in the Ashland region.

**Director Martin Pays City Employees.**—It is stated that Director Martin has advanced $4,000 to complete the June and July pay rolls of the employes of the Municipal Hospital. The $15,000 appropriated by Councils was exhausted when the June pay roll was but half completed.

**Filtered Water Above Standard.**—Chief Hill of the Bureau of Filtration, declares that the best results ever obtained outside of a laboratory by a slow sand filtration have been reported to him by the engineers in charge of the Upper Roxborough plant. Schuylkill water containing 42,000 bacteria per cubic centimeter was purified by the sand bed completed a week ago so that the bacteria were reduced to 12. The highest amount left by any of the beds is 60 per cubic centimeter.

**Queer Verdict in the Ball Park Disaster.**—The Coroner's jury which investigated the recent disaster at the Philadelphia Ball Park by which 12 people lost their lives, found that the accident was due to the rotten condition of the supporting timbers of the stand. They recommend an increased number of building inspectors and that the inspectors be given more power. The queer part of the verdict was that the Philadelphia Base Ball Club, the former owners, was found responsible in not having made a thorough investigation of the timbers in the stand during its ownership and in stating at the time of transfer that the buildings on the ground were in first class condition. The verdict against a corporation that has passed out of existence is considered remarkable.

## CHICAGO.

**Hospital to be Enlarged.**—Alexian Brothers' Hospital has purchased a plot of land adjacent to the hospital, 485 by 125 feet, for $10,000.

**Appointment of Dr. Riebel.**—Dr. Ernst Riebel has been appointed an associated member of the County Hospital surgical staff.

**General Hospitals Require no Frontal Consent.**—Acting Corporation Counsel Fyffe has given an opinion to the effect that general hospitals are not required to secure the frontage consent of residents in the same block in order to build. Hospitals for the insane, inebriates and the treatment of contagious diseases require frontage consents.

**Impure Milk.**—Out of 760 samples of milk and cream analyzed in the Laboratory during the week, 60 were found below grade. Among these 760 samples from all sources there were 112 taken at the trains—before the milk had come into the possession of the city dealer. Out of these 112 samples four were found below the standard of butter fat, and 40 below the standard of total solids.

**Typhoid Fever.**—Although the anticipated increase of typhoid fever has resulted to quite as great an extent as was feared from the pollution of the city water several weeks since it has not yet been reflected in the mortality. Nearly all hospitals report an increase of cases—the net figures being about 28 per cent. greater than for the previous week. But the typhoid deaths reported are decreasing—only 8 during the week against 11 the week before, and 45 in the corresponding week of last year.

**Smallpox.**—Ten new cases of smallpox have been discovered and removed to the Isolation Hospital. The Chief Medical Inspector dwells upon the fact that none of these had ever been vaccinated, and that 7 of them were children ranging in age from two months to six years. The type of the disease this year is much more serious than last year. In 1902 there were 338 cases with only 5 deaths—a mortality rate of less than one and a half per cent. Thus far this year there have been 346 cases and 45 deaths—a mortality rate of 13 per cent.

## GENERAL.

**Electro-Therapeutic Association.**—The annual meeting of the American Electro-Therapeutic Association will be held at Atlantic City, N. J., September 22, 23, and 24, 1903. An unusually attractive program has been provided.

**Virginia Medical Society.**—The thirty-fourth annual meeting of the Medical Society of Virginia will occur at Roanoke, September, 15, 16, and 17, 1903.

**International Dermatological Congress.**—The fifth International Dermatological Medical Congress will meet in Berlin, Germany, September 13 to 17, 1904. The following subjects have been selected by the officers of the Congress for discussion: (1) The syphilitic affections of the circulatory apparatus. (2) The diseases of the skin in anomalies of metabolism. (3) Epitheliomas and their treatment. Dr. James Nevins Hyde, of Chicago, is secretary for America.

**International Congress for the Study of Tuberculosis.**—This congress will be held in Paris, September 24 to October 1, 1904. Subjects for discussion and special report will be: (1) Treatment of Lupus by New Methods ;(2) Early Diagnosis of Tuberculosis; (3) Comparative Study of the Various Tuberculous Affections; (4) Etiological Factors in Tuberculosis; (5) Value of Different Methods of Treatment of Tuberculosis. There will also be a technical section which will provide a scientific collection comprising anatomopathological, histological and bacteriological exhibits, statistics, plans for hospitals, sanatoriums and dispensaries, publications, and documents of antituberculous leagues, etc.

**Medical Care of Indigent Women in Algeria.**—In order to insure proper medical care for indigent women who cannot or will not, by reason of their special customs, consult a male physician, the French government is seeking to organize in all Algerian towns in which the Moslem population is of sufficient numerical importance, a corps of women physicians for the gratuitous treatment of such patients. A salary, proportionate to the amount of work done, will be paid, and a residence, medicine and instruments supplied. A dispensary has already been established in Algiers and Blidah; and others are to be opened in Oran, Tlemcen, Mascara, Mostaganem, Miliana Bône and Bougie.

**Plague Victims Die.**—Two of the bubonic plague victims on El Bajio ranch have died. The third patient has a chance of recovery. No other cases have been reported. Health authorities are confident there will be no spread of the disease. Stringent quarantine has been enforced and the houses occupied by the patients have been burned. Similar precautions were most successful in preventing the spread of the plague in Osos during the Mazatlan epidemic. El Bajio ranch is close to Sequeiros, Mexico, where the

last case of the plague occurred during the recent epidemic.

**Street-Car Accidents.**—Seven deaths per month by street-car accidents have been the average in St. Louis since the opening of the present year. The City Council has appointed a special committee to ascertain whether they were due to the lack of stringent laws, the non-enforcement of the present laws, the lack of efficient brakes and fenders, the carelessness of the motormen and conductors, or the employment of incompetent men by the street-car companies. The introducer of the motion stated that he had been in five street-car accidents himself in the past four weeks, and was convinced that, in many cases, carelessness alone was the cause.

**Protects Children's Health.**—Deputy Health Inspector Ferdinand Sauer of Jersey City yesterday reported to the Health Board that since the issue of the order suspending the sale of "apples on a stick," gastritis among children had almost entirely disappeared. Before the order the disease was epidemic in the Hudson City district and prevalent in other parts of the city.

**Pure Water for Ithaca.**—Assurance against a repetition of the typhoid fever epidemic of last March was given to the citizens of Ithaca this week when the Ithaca Water Company commenced pumping water from its new filter station into the city mains. For four days the officials of the company and the expert engineers from New York and Philadelphia have been testing the workings of the plant, but there was no announcement that the pumping of water would begin until last Sunday, when the news that purified water was at last to be had spread rapidly through the city, and thousands of people came to visit the plant. Six months ago Cornell University loaned the water company $150.000 for the building of the purification plant, and since that day there has not been a moment when men were not at work on it. The plant is pronounced by Dr. George A. Soper, representing the State Board of Health, to be a perfect piece of work.

**Grievances of the Indian Medical Service.**—Loud expressions of dissatisfaction with the rewards for their labor are heard at the home office from members of His Majesty's Indian Medical Service. Chief among the general grievances is slowness of promotion. As things are at present no officer can get the promotion which he has a right to expect until he has served for about thirty years. Expressed in terms of money this means that all officers who entered the service over the age of 25—that is to say, most of those now entering—can look forward to a pension of only £500 instead of £700, or possibly £950. It is suggested that all officers should be allowed to complete 30 years' service before compulsory retirement, and that every year's service over 25 should qualify for an additional £40 a year. Another grievance is the inadequacy of the present scale of pay. A class of educated native practitioners have created, and they not unnaturally get the larger part of the private practice which used to form a substantial addition to an officer's pay. Then the depreciation of the rupee causes a loss of about one-third of the pay as originally fixed. It has been urged, therefore, that the pay should be increased proportionately with that of the Royal Army Medical Corps.

**Mr. Edison in Medicine.**—Thomas A. Edison, the inventor, announced on last Thursday that he had branched out temporarily into medicine and had made a study of a cancerous growth which started on the arm of his assistant, after he had been burned by Roentgen rays. The inventor says he thinks he has hit upon a cure for similar cancers, although he will let the surgeons and scientific physiologists work out the problem. Mr. Edison's theory is that any cancer which begins on the surface, can be cured by the introduction of fresh blood from a healthy subject into the blood of the person affected.

**Memorial Fund in Honor of Dr. Reed.**—On August 15, a meeting was held in Bar Harbor, of friends of the late Major Reed, M.D., U.S.A., to whom in a large degree is due both the discovery of the mode by which yellow fever has been spread, and also the consequent suppression of that dire disease. Representative men were present from different parts of the country and letters were received from various members of committees already appointed to promote the collection of a memorial fund in grateful commemoration of Dr. Reed's services. Important suggestions were presented from President Eliot, Dr. W. W. Keen, Prof. J. W. Mallot and others. Dr. Daniel C. Gilman, chairman of a committee appointed by the American Association for the Advancement of Science, presided, and Dr. Stuart Paton acted as Secretary. Among those who took part in the conference were Dr. W. H. Welch, of Baltimore, Dr. Janeway, of New York, Dr. Abbott, of Philadelphia, Dr. Herter, of New York, Dr. Barker, of Chicago, Dr. Putnam, of Buffalo, Dr. Fremont Smith, of Bar Harbor, and Dr. Sajous, of Philadelphia, and besides these medical gentlemen, Bishop Lawrence, of Massachusetts, and Messrs. Morris K. Jesup, President of the New York Chamber of Commerce, John S. Kennedy, President of the Presbyterian Hospital of New York and William J. Schieffelin, of New York. The following conclusions were reached: That an effort should be made to raise a memorial fund of $25,000 or more, the income to be given to the widow and daughter of Dr. Reed, and after their decease the principal to be appropriated either to the promotion of researches in Dr. Reed's special field, or to the erection of a memorial in his honor at Washington.

Arrangements were made for the publication of circulars explaining this movement, and asking cooperation not only from the medical profession, but from all liberally disposed individuals who appreciate the value of Dr. Reed's services to mankind.

**X-Science Not for Animals.**—The Texas District Court at McKinney has decided against Christian Science as the proper treatment for animals. The case came from the county court in a suit brought by a farmer of Collins county against the Houston and Texas Central Railroad for so injuring his horses with a train that they died. The testimony was straight, and it seemed that the plaintiff would win his contention without doubt. He went on the stand in his own behalf, and what he said in answer to questions strengthened his case until the attorney for the railroad asked him what treatment he had given the horses. He answered that he had given them the Christian Science treatment only. He had prayed for them, but had put nothing on their wounds and had done nothing to relieve them. The jury returned a verdict for the railroad company.

**The Heroic Death of Dr. Salazar.**—Dr. Salazar, physician in charge of the American Hospital in Tampico, has given his life in a brave fight to check the yellow fever epidemic. No death of the summer has caused more grief among the classes with whom he labored, while the manner of his death has excited the greatest possible admiration for his bravery. The physician's labor during the epidemic was unremitting. Despite the warnings of friends he persisted

in working by the bedside of his patients long hours, sometimes without food and always without proper rest. To the American colony he was most assiduous in his attentions, and his direction of the hospital brought it to a high state of sanitary perfection. Dr. Salazar detected symptoms of the fever in himself less than a week ago, but not until the disease had progressed far did he relinquish the direction of his staff. Then he turned to studying the state of his own disease, noted every advance, and at the last cooly called for pen and paper and wrote his own death certificate. Since his death to-day the Mexican health authorities have made a careful inspection of the American Hospital, and their report declares it to be in an excellent condition.

**Obituary.**—After an illness of two days Dr. Phanelt Coe Barker, founder of Morristown Memorial Hospital and dean of the medical profession in Morristown, N. J., died in that city August 21 from angina pectoris. He was sixty-eight years old, and went to Morristown about forty years ago. Twelve years ago he founded the Morristown Memorial Hospital Association, which built the Morristown Memorial Hospital, the finest institution of its kind in Northern New Jersey. Every day up to a week before his death Dr. Barker made a personal visit to the hospital.

## CORRESPONDENCE.

### OUR LONDON LETTER.

(From Our Special Correspondent.)

London, August 8.

THE ANNUAL MEETING OF THE BRITISH MEDICAL ASSOCIATION—CANCER RESEARCH—THE LISTER INSTITUTE.

The annual meeting of the British Medical Association which took place at Swansea last week was the first held under the reformed constitution. Some anxiety was felt by those responsible for the new organization as to the working of the somewhat complicated machinery which has been devised to enable the Association to give expression to its corporate wishes. All went off without a hitch, however, mainly owing to the tact and moderation of Sir Victor Horsley, who was elected Chairman of the Representative Meeting which now controls the political action and general business of the Association. Neither tact nor moderation has hitherto been among the characteristics of Sir Victor Horsley in his public capacity, but his experience of practical affairs appears to be teaching him that the methods of the irresponsible agitator are out of place in a responsible official. Thiers tamed Rochefort, whom he had described as a *fou furieux*, by giving him a place in his government; and it may be hoped that a like cause may transform Horsley from a demagogue into a statesman. At any rate if the Representative Meeting under his management did nothing very remarkable, it must be allowed the credit of having done something, and that in itself is a novelty in the history of the British Medical Asociation sufficient to justify us in regarding this year's meeting as epoch making. The fundamental reform in the constitution of the Association is the transference of the center of power from the members in Annual Meeting assembled—which was little more than a fortuitous and momentary concourse of atoms—to a body of representatives elected by the Branches and sent by them to be the mouthpieces of their views. From the purely theoretical point of view this seems to be a distinct improvement, but in practice it will probably mean nothing more than a change in the name of the governing body. The real obstacle in the way of all useful reform is the profound indifference with which the whole matter is regarded by the bulk of the members. The fact is, medical politics are scarcely considered respectable by the majority of practitioners who have plenty of professional work to keep them busy. It is the young men who have nothing to do who naturally find time to occupy themselves with public affairs. *Plus ça change, plus c'est la même chose.* The British Medical Association, whatever may nominally be its form of government, must always be under the direction of an active minority. Of the scientific side of the meeting there is not much to be said. It is the rule of the Association that each year its President should be chosen from among the local luminaries, who, in a place like Swansea, are naturally not stars of the first or even of the second magnitude. The President this year is a worthy general practitioner whose address was marked rather by strong practical sense than by original thought or philosophic breadth of view. His best point was in reference to the fallacy of estimating the sanitary condition of the country by the general death-rate. A decline in the rate has, he said, perhaps tended to blind us to facts which lie a little below the surface. It is true that during the last thirty years the annual death-rate of all ages in England and Wales has fallen from 22.25 to 16.3 per thousand living, a gain of about 26 per cent.; but on the other hand the death-rate of infants under one year of age has risen nearly 2 per cent., while the birth-rate has diminished. Nearly half the total number of children born are dead within five years. The increased mortality among infants is due to diarrhea and enteritis, and the increase due to these causes is seven times greater in towns than in the country. Moreover, the mortality from diarrhea is much greater among infants artificially fed than among those fed at the breast. Although much of the mortality is due to the ignorance or carelessness of mothers, Dr. Griffiths sees in it an illustration of a defect in our sanitary administration. Our regulations as to the conduct of dairy farms and other matters vitally important to the health of infants are mostly of an optional character, and the local authorities in too many cases do not enforce them. In its social aspects the meeting was very pleasant. One of the most enjoyable entertainments was a visit to the Goddess of Song, Madame Patti, in her fairy bower at Craig-y-Nos. One of those privileged to see her in her home informed me that she is likely to visit America again before long. The annual meeting next year is to be held in the historic University town of Oxford.

The epidemic of cancer cures continues. This very day we are informed by the daily papers—which of course have the statement from "an authoritative source"—that Dr. Bashford, Director of the work done under the auspices of the Cancer Research Fund, and his assistant, Dr. Murray, have solved the mystery of the causation of cancer—or are on the eve of a great discovery. But alas! so many have with equal confidence proclaimed that they had found the answer to the riddle that one may perhaps be pardoned for feeling a certain skepticism as to the success of the most recent claimants. There is all the more reason for doubt, since only a few days ago, on July 30, a meeting of the Cancer Research Fund was held under the presidency of the Prime Minister, Mr. Arthur Balfour, at which a report was presented by the aforesaid Dr. Bashford in which the results of the investigations so far undertaken, were set forth but no mention was made of the momentous discovery in question. Indeed, the report dealt much more with work to be done than with anything yet acomplished. This is scarcely

to be wondered at, considering that the scheme of organized research is as yet scarcely "in being," and its operation is still seriously hindered by lack of funds. Of the capital sum $500,000, which it was estimated would be required for the effective prosecution of the work only a trifle more than a half has up to the present been subscribed. Doubtless it was for this reason that the Committee invited the aid of Mr. Balfour's persuasive eloquence, and if one were dealing with an enterprise under less august auspices, one might be tempted to suspect that the announcement of Dr. Bashford's discovery was made at what is thought to be the psychological moment for the same purpose. Some justification might perhaps be found for such a suspicion in the suggestive manner in which the hint that we are on the verge of a great revelation is coupled with a delicate reference to the hindrance to research caused by want of funds. One of the most important parts of the report is that dealing with therapeutics, the results of the Finsen light treatment, high-frequency currents and X-rays—methods somewhat oddly grouped together under the head of electrotherapeutics—have been the subjects of inquiries directed to those in charge of special departments at hospitals. Reports of some 400 cases have been submitted for the consideration of the Cancer Research Committee. The results of the treatment of rodent ulcer by means of X-rays are confirmatory of previous experiences. It is said that recurrence occurs in from 20 to 40 per cent. of the cases, but are as a rule as amenable to treatment as the primary disease. Complete healing was obtained in 141 out of 216 cases, of which detailed reports were sent to the Committee. This gives a proportion of 65 per cent. of successes. It is pointed out that as the majority of cases were inoperable or had already been treated by the knife and had recurred, this high percentage is very satisfactory. Of the remaining cases, improvement was recorded in 43, no benefit resulted in 16, while in 3 instances the disease was aggravated. With regard to other forms of malignant growth, the Committee state categorically: "The results so far brought to our notice do not establish the efficiency of any of these measures as curative measures in sarcoma and carcinoma." In view of the very many statements recently made in the high-class newspapers to the effect that the Committee would recommend high-frequency currents as the true and only cure for cancer, this pronouncement should be read, marked, and inwardly digested by the journalists who seek inspiration in medical matters from doubtful oracles. An especially satisfactory feature in the report is the indication of the fact that an exhaustive investigation on cancer in animals and its relation to the disease in human beings has been undertaken.

The Jenner Institute of Preventive Medicine is henceforth to be known as the Lister Institute. This change of patronage, which has been made with the reluctant consent of Lord Lister, is not due to any decay in the fervor of the cult of Jenner. The reason is that another Jenner Institute, which is a purely commercial concern, whose business is the manufacture of vaccine lymph, has been in existence for some years, and as the Institute of Preventive Medicine also manufactures lymph, there was frequent confusion and occasional conflict between the two establishments. London now has a Lister as Paris has a Pasteur Institute. The Lister Institute is well endowed, thanks to the munificence of Lord Iveagh who two or three years ago gave it $1,250,000. There is a close connection between brewing and bacteriology; hence there is a special appropriateness in the benefaction of Lord Iveagh, whose patronymic is Guinness, of double Stout fame, to an institute founded for bacteriological research.

## OUR VIENNA LETTER.

(From Our Special Correspondent.)

VIENNA, August 2.

EXAMINATION REGULATIONS IN AUSTRIA—WEIMAR UNIVERSITY—TRACHOMA IN THE AUSTRIAN ARMY.

THE Minister of Education edited the new examination regulations on December 21, 1899. These have been made chiefly according to the propositions of Exner, the secretary of the Minister. He also proclaimed in the society of Vienna physicians this new system, and was confronted with a sharp critique from an illustrious member of the Professors of the University. When the new regulations were first carried out, the students started a powerful movement against them.

The Professors of the University sympathized with the students, and to this fact was due that the Minister determined to make essential alterations. These were proclaimed on April 14, and their chief points are as follows: (1) The candidate who wishes to acquire the doctor diploma has to spend ten half years in the medical faculty, and pass three examinations; (2) The number of weekly compulsory lecture hours is 20, with the exception of one semester, when it is reduced to 16. (3) Semesters which were spent in foreign universities can be accepted only if the Minister and a committee of Professors give their consent. (4) Previous to the first examination the student has to attend lectures through four half years, of which two winters must have been spent in the dissection room. (5) Subjects of the first examination are: general biology, medical physics, medical chemistry, anatomy, histology, physiology; the first two subjects are theoretical, the others practical. (6) The second and third examinations can be passed after the finishing of the tenth half year. During the last three years the attendance at the following lectures is compulsory: Internal medicine and surgery, obstetrics and gynecology, ophthalmology, rhinology, otology, and dentistry, also vaccination. (7) The subjects of the second examinations are: Pathological anatomy and histology, general and experimental pathology, pharmocology and prescription, medicine, study of mental and nervous diseases; the second and third subjects are theoretical, the others practical. (8) The subjects of the third examination are: Surgery, obstetrics and gynecology, ophthalmology, study of venereal diseases, dermatology, public hygiene, medical jurisprudence; the last two subjects are theoretical, the others practical. (9) The censors have to pay attention that the candidate may be sufficiently expert in anatomy and physiology. (10) The whole subject of an examination must be laid down within six months. (11) All the examinations must be passed in the same University; only in exceptional cases is it granted (with the consent of the Minister) that one of the examinations shall be passed in another University.

The Weimar Ministry issued this decree, under the title, "What Shall We do In order to Remain Healthy?" comprising 21 hygienic rules, which I give in condensed form, as follows: (1) Take a daily bath; (2) wash your hands often, keeping your finger-nails trimmed and clean; (3) keep your mouth scrupulously clean and brush your teeth after every meal; (4) make your toilet before coming to school; (5) keep your clothing dustless; (6) white garments should be changed often; (7) clean your feet before entering school; (8) refuse of any kind must not be brought to the schoolroom; (9) never expectorate on the floor; (10) remove your outer garments on entering the schoolroom; 11 to 21 deal in the acquirement of plenty of fresh air; school-

rooms should be aired during recess; don't go too long without eating; walk and stand erect; never cross your legs; neither write nor read in dim light; and finally, complain to the schoolmaster if your place is either too cold or too warm, if you don't see or hear well, also notify the schoolmaster if there is infectious or contagious disease near your home.

There are between two and three thousand cases of trachoma in the Austro-Hungarian army. This vast number of cases induced the energetic interference of the Minister of War. He requested the Army medical staff to plan a method to obstruct the propagation of this terrible disease. Here is one of the methods: To concentrate the afflicted persons to one place, and to watch that no new trachomatic patient shall be allowed to enter military service.

### BYWAYS OF MEDICAL LITERATURE.—XVI.

#### FROUDE'S VERACITY AS A PATHOLOGICAL STUDY.

SIR JAMES CRICHTON-BROWNE, M.D., has recently written an introduction to the new letters and memorials of Jane Welsh Carlyle, which are sure to overcome the prejudice created against Thomas Carlyle for his supposed unfeeling treatment of his wife as depicted by Froude's work on their domestic relations. Dr. Crichton-Browne is one of the most distinguished alienists in England, and his essay may well be considered a study in the pathology of lying with James Anthony Froude, the historian as the basis for his study. Froude, though one of the most picturesque and striking English writers of the last generation, and a man whose historical research should have given him a permanent place among the great writers of history, was constantly prone to be led away by his feelings into the expression of opinions for which no one else could find any foundation, but which Froude bolstered up by means of garbled quotations, special points of view and the hundred ways that a prejudiced man has of making his opinion seem justifiable. His picture of Henry VIII. as a hero was the most flagrant example of this, and has been properly labeled by such distinguished historical investigators as Green and Freeman.

It was a shock to the literary world some years ago to find that the domestic life of the Carlyles had been apparently intensely unhappy. Froude edited the letters of Mrs. Carlyle and made it very clear that she lived in a chronic state of unrest and conjugal discomfort. As a matter of fact there proves to be no foundation at all for such an opinion. Carlyle was a loving husband, as husbands go, and Mrs. Carlyle was herself not a little to blame for whatever of unhappiness there was, and seems also to have been one of those on whom imaginary ills, as women occasionally will feign them, had not a little effect. The review of the whole subject will unmake the false impression created by Froude's work and adds a new and piquant feature to the psychology of veracity and of lying. It is evident that some, gentlemen though they may be, and with the best of intentions and apparently with the best of information, will still be sure to see things awry as regards ultimate truth and to express themselves in such a way as to deceive others as regards the actual facts. We might ask them in view of this new evidence what becomes of the "Gouldian" phantasy regarding "eye strain" as a cause of conjugal infelicities?

#### IMMUNITY TO BEE STINGS.

There has long been a tradition that those who associated much with bees so as to be frequently stung by the insects gradually acquired an immunity to their severer effects, at least. This fact is confirmed by the observations of Dr. H. F. Parker, who devotes some time to bee culture in the neighborhood of Indianapolis. He relates his experience with bees the first year and the intense discomfort occasioned thereby. The stings lost some of the acuteness of their effects in the course of time, but this he attributed to his growing accustomed to them. In the second year, while transferring a swarm of bees, he was stung many times with very little pain or tissue reaction. He says:

"Sting followed sting in succession, in legs, arms, fingers, neck and face. I imagined what a picture I would present—closed eyes and swollen hands and feet. I worked on, and so did the bees. I could feel the needle-like thrust, but then it did not seem to pain as much, and at last I finished the task. With aching head, slight nausea and vertigo slowly coming on, I left my task with a sigh of relief for what was accomplished and filled with wonderment as to what my personal appearance would be.

"Imagine my astonishment to find merely slightly raised red spots, like little pimples, with the red sting in the center, as the result of each and every sting. I must have had something like forty of them on various parts of my body. My clothes were full of them; but, they being so thick, did not allow the sting to penetrate. The dizziness, nausea and headache left me and 'Richard was himself again.'

"When I again visited my bees I did not dread the stinging properties any longer, at least, not as much so as formerly, and then, and ever since, I have found that when a bee does sting me the pain is only sharp for an instant and there is an absence of the after-swelling.

"I have since been stung many more times than I was at that time, and yet none of the symptoms above referred to have been reproduced. Am I not, therefore, immune of the poison of the honey bee, at least to a certain extent? I firmly believe that the beekeeper becomes inoculated with the poison of the bee, and usually becomes proof, or at least immune, against it, is no more to be doubted than the fact that vaccination is a preventive against smallpox."

It is not surprising that bee stings should thus develop a protective immunity to their effects. Practically any poison thus introduced into the system in amounts insufficient to cause serious disturbance is followed by a protective reaction. The method of protecting small animals from snake poison and producing antivenene is founded on this fact. The stings of insects such as the flea and the mosquito produce in many individuals especially susceptible to their stings a corresponding protective effect if the person attacked stays in the neighborhood long enough.

#### SIR WILLIAM SMYTH.

The following verses were read at the unveiling of a memorial window in stained glass in the Ulster Medical Institute of Belfast, Ireland, only a short time ago. The window commemorates, with proper symbolism, the noble conduct of Dr. William Smyth, during an outbreak of typhus fever on the Island of Arranmore, off the coast of Donegal, one of the northern tier of Irish counties. Dr. Smyth was the nearest physician to the Island, and when asked to give his services rowed daily from the mainland, carrying not only medicine, but food to the fever-stricken peasants. His patients were so poor that he could never hope for anything more than gratitude from them. There was the greatest possible fear of infection throughout all the adjoining countryside. Typhus is still well known and much dreaded in three countries of Europe, Hungary, Russia and Ireland, and its well known contagiousness prevented him from obtaining help. Finally Dr. Brendan McCarthy, the medical inspector of the local government board, of-

fered his services for the relief of the afflicted patients. Together the two physicians obtained an old, leaky, abandoned boat, the only one procurable under the circumstances, and in this they carried the patients to the mainland. The boat leaked so badly that they were in constant danger of foundering. The old craft actually did sink, shortly after they had landed. Dr. Smyth caught the fever, and owing mainly to the fact that his efforts in behalf of his patients had weakened his resisting powers, he succumbed. All of his patients recovered. The verses which we reproduce here are, we consider, one of the best examples of medical memorial verse that we have seen in recent years. The story and its worthy commemoration deserves a place in the scrapbook of every practitioner of medicine, as a testimony to the fact that even in these sordid modern days the true professional spirit is able to raise men above the tendencies of the times and make them heroes in the highest sense of the term:

### THE MEMORIAL WINDOW.*

The veil is drawn—and from the jewelled pane
Flashes on straining eye and beating heart,
Emblazoned by the Limner's loving art,
A story fashioned in heroic strain.

Yet this, no fabled feat in days of yore,
No mythic song, nor legendary lay,
But all-true tale of this our later day,
Amid the wastes and wilds of Arranmore.

A lonely islet in the western wave,
Lashed by Atlantic surge and winter storm,
Through it came stalking Fever's spectral form,
Gathering her tribute for the yawning grave.

And men fled shuddering from her pathway—
Men fled, save only one, a man of men,
Who, lion-hearted, leapt into her den,
And battled with her for her anguished prey.

Alone across the strait his skiff he plied,
And knelt beside the sufferer's bed alone,
Till one, with heart undaunted as his own,
Sprang to the place of peril at his side.

And while the billows break on Arranmore,
Men still shall wond'ring tell, and wond'ring hear
How in a wave-worn barque of yester-year,
They piloted the sick from shore to shore.

No thought was theirs of home, of child, of wife,
Of worldly guerdon, or of worldly fame,
But theirs the spirit rapt, the heart-aflame
To render up, so others lived, their life.

And life from one was called for, and laid down
By him who first had braved the Fever foe.
His fellow wears the laurel here below;
But his the martyr's palm, the martyr's crown.

Alone he now hath voyaged forth again,
And ferrying o'er the unfathomable tide,
Beholds, encircled by the glorified,
The Sovereign Healer of the whole world's pain.

—Frederick Boas, F.R.U.I.

#### WEATHER PROGNOSTICATION AND ACHY FEELINGS.

Now that we no longer have any confidence in the moon or the special appearances of the clouds at night with regard to the moon, as having any significance for the weather, there is need of something else on which to base predictions since human nature is prone to prophesy. A writer in the New York *Independent*, for July 16, 1903, describing a summer's day in the country, suggests that while the clouds may mean much and such expressions as "the swallows fly low," "the cat eats grass," "the smoke drops down from the chimney," are all the crystallized wisdom of weather prophets from time immemorial, yet after all "the best rain prophesy that I know," he says, "is nerve irritability. If the boys are easily provoked (myself also) there is likely to be a shower."

Here is a weather prophet with ideas worth considering. Sometime it will come to be realized that many of the pains and aches that immediately precede and accompany damp weather, are not due to rheumatism, nor to the rheumatic diathesis, but are just plain everyday irritability consequent upon some change in nervous conditions which are caused by a drop in the barometer perhaps, or perhaps the hydroscopic variation in tissues which follows a change in the atmospheric humidity. Old people become walking barometers in their power to portend storms because the lessened elasticity of their arterial and vascular system prevents or at least hampers those changes in the peripheral circulation which would compensate for variations in barometric pressure. Whenever an injury has taken place around a joint this same state of affairs proclaims itself even in comparatively young subjects. All signs, however, fail in a dry time, so that the human barometer, like most other weather prophets, proves unreliable when it is most needed. It is probable, however, that a careful study of human feelings would enable the would-be weather prophet to prognosticate weather conditions with more assurance than any empirical study of the moon and cloud conditions.

* We owe our copy of the verses to the Irish Monthly, so ably edited by the brother of the late Chief Justice Russell.

## SOCIETY PROCEEDINGS.

### BRITISH MEDICAL ASSOCIATION.

*Seventy-first Annual Meeting, Held in Swansea, July 28, 29, 30 and 31, 1903.*

(Continued from Page 383.)

**Inquiry into the Relation of Vaccination to Infant Mortality and Acute Concurrent Infantile Diseases.**—Dr. J. M. Mackenzie of Kirkby-in-Ashfied said: "The lay mind is largely impregnated with the idea that not only is vaccination injurious to infant life—that is, that vaccination introduces into the infant's system many diseases which, by their manifestation from time to time, mostly in a chronic form, impair the individual's vitality and render life a burden, but furthermore it is believed that the vaccination process in itself is directly contributory to infant mortality. This last impression is the product of the conflict of medical evidence as observed at public inquests over infants dying soon after vaccination. The well-informed, who readily consent to their children being vaccinated, have a lingering suspicion that the process of vaccination has its origin in the barbarism of the past, and although they admit that the evidence in its favor as a preventive against smallpox is overwhelming, they are still imbued with the impression that many infant maladies follow in its train. The militant antivaccinator, conscious of this state of public feeling, finds his mission in palming off on a too credulous public fables, fancies, and surmises, too often colored by the individual opinions of a few medical practitioners, who may be for the time being—as, for instance, at public inquests—opposed to the vaccinator. Medical questions, especially those of a clinical nature, have always been misunderstood by the laity,

the educated among them as well as the ignorant, hence the physician, with serene confidence in the value of his art, may well afford to go about 'having compassion on the ignorant and those that are out of the way.'

"One is differently impressed when one finds among the followers of Æsculapius the same heterodox teaching. A few years ago I had posted to me a lecture on infant mortality by one who stands high in the profession as a specialist in public health, originally addressed to a lay body, a municipal corporation, who, it may be presumed, received its statements as incontestable, not falling within the domain of dispute. To my surprise I found that in describing the causes of infant mortality vaccination was given as one. Although unable to find that the writer had any very large experience in the work of vaccination or the treating of infants, yet the bare statement that vaccination was a cause of infant mortality made a far deeper impression on my mind than all the arguments of the antivaccinators I have encountered, and they have not been few. Engaged as I have been now for several years as a medical officer of health and public vaccinator to a fairly large urban district, I resolved to find out for myself, as far as reliable statistics would allow me, how much truth there might be in the allegation. The material for the task lay ready to hand, even if it involved a good deal of labor in classifying and tracing all the cases dealt with. In the first place, the registrar for the district provided returns showing date of birth, name of child and parent, residence and where born, for the last three years. The vaccinating officer, on the other hand, placed at my disposal his registers showing the number vaccinated and unvaccinated in the urban district for the same period. As medical officer of health, I received weekly returns of all deaths taking place therein, so that material for the inquiry was complete. Obviously, certain exceptions had to be made, so as to remove as far as possible sources of fallacy. (1) All infants dying under one month were not included, inasmuch as it was found that no child was vaccinated under one month. (2) All infants, whether vaccinated or unvaccinated, who were not born in the district, were excluded, although such were included in the vaccination and death returns, they were absent from the birth returns, and hence could not be dealt with. (3) All who had left the district, whether vaccinated or unvaccinated, were excluded, as it was impossible to trace what happened to them.

"The sifting process, beginning with January, 1900, and ending with July, 1902, left 987 infants to be accounted for whose fate up to the age of twelve months was ascertained in every single instance. In 1900, 329 infants were accounted for, of whom 242 were vaccinated, and of these last 22 died before reaching the age of twelve months, giving a death-rate of 9.09 per 100; for the same year 87 unvaccinated were traced, 13 of whom died before reaching the age of twelve months, being a percentage of 14.94. For 1901, 398 were traced, of whom 264 were vaccinated and 134 unvaccinated. Of the 264 vaccinated, 22 died before reaching the age of twelve months, yielding a death-rate of 8.33. Of the 134 unvaccinated, 22 died, a percentage of 16.41. For 1902, 260 were traced, of whom 200 were vaccinated and 60 were unvaccinated. Of the 200 vaccinated, 16 died before reaching the age of 12 months, yielding a death-rate of 8.00. Of the 60 unvaccinated, 10 died; a death-rate of 16.66. Taking the death-rate for the three years among the vaccinated and unvaccinated, we find the vaccinated yield a death-rate of 8.49 and the unvaccinated 16.01. It will be found on comparison that the death-rate among the vaccinated and unvaccinated varies but little in different years; that is to say, it does not fluctuate. Again the death-rate among the unvaccinated is practically double that among the vaccinated. An explanation of this may be impossible in the limited time at one's disposal, but will be briefly considered further on when discussing the social conditions and neurotic characteristics of those generally found as extremists, antivaccinators included.

"As the main object of this paper is to discover any connection between vaccination and infant mortality, it is necessary to group: (1) The vaccinated according to the age at which vaccination was performed. (2) Deaths among the vaccinated at various ages. (3) Intervals between the vaccinal process and death. (4) Deaths among the unvaccinated at various ages.

"If we compare the death-rate from the more common causes of infant mortality an interesting difference in favor of the vaccinated will be found:—Bronchitis and pneumonia claim 36.13 per 1,000 of the vaccinated against 39.57 for the unvaccinated; marasmus, 5.66 for the vaccinated against 39.57 for the unvaccinated; convulsions, 2.83 for the vaccinated against 10.67 for the unvaccinated; diarrhea, 14.16 for the vaccinated against 35.59 for the unvaccinated; and so on.

"Having regard to the great difference in the death-rate, it is necessary to give what I consider to be the explanation of this difference. Be it noted that I do not claim that vaccination keeps babies alive, but I suggest that the facts disclosed show it does not kill them. The first thought occurring in one's mind is that the unvaccinated are the unhealthy—the children of poor and ignorant people, who take little care of their offspring—and that the incidence of any disease falls more heavily upon them, and hence would account for the difference in the death-rates. From very intimate knowledge of the social condition of the parents of every child that died I am certain that this is not the explanation. Bearing on this aspect of the question, a factor of the greatest importance in the problem is that 94.4 per cent. of the vaccinations under consideration were performed by the public vaccinator, and that at least 30 per cent. of them were among the very poorest of the poor—the casual laborer, the out-of-employment, the ill-housed, ill-clothed, and ill-fed, the children of young people too early married, with neither means or knowledge for rearing up healthy children. We know that among such infantile mortality is alarmingly high. On the other hand, two-thirds of the unvaccinated were the children of conscientious objectors, who obtained their certificates of exemption. The antivaccinators in the district are found among the well-to-do of the working classes, the superior artisan, the small shopkeeper, the intelligent, if argumentative, teetotaler. I have often observed that these extremists were of a neurotic type, easily excited against anything that had the appearance of compulsion. There is a nervous tension in their ethical code which bespeaks instability and lowered vitality; their children die, not from want of care and nutrition, but by inherent constitutional defects. In the early years of their married life they had their children vaccinated, and after their death they quickly jumped to the conclusion that it was due to vaccination, and determined there and then, as if with a sacred vow, that no more of theirs should be vaccinated. This tradition passes from mother to daughter, and still their children die, probably in the same proportion.

"The next point in the explanation, and by far the most important is that the practitioner is extremely discriminating, and does not vaccinate the weaklings—that is, those likely to die within a year. The more care taken in this direction the higher the death-rate among the unvaccinated, as against the vaccinated.

"A popular impression, even among the profession, is that the vaccinal process acting concurrently with another disease imparts a shock to the infant, thereby accelerating its death. This statement is made with all the more show of authority if the infant is in delicate health. Almost every week instances of this description are reported in the newspapers, whereas as a matter of fact the vaccinal process is remarkably gentle in its onset, ushered in by no shock; there is nothing to be observed corresponding with the rigors of adults or the convulsions of infants at the onset of acute disease, for example, pneumonia.

"There is an even, gradual rise of temperature up to 100° or 101° F., with a quickened and full pulse; moreover, be it particularly observed that in delicate children and very young infants the vaccinal process with its accompanying symptoms is milder, and on the whole longer, than in the robust and more advanced in age. Instead of being a danger when running concurrently with other acute diseases, I believe it to be beneficial in many, and to tone down the symptoms of both pathological conditions, namely, the vaccinal process and the acute disease. Let me give a few instances: Beginning with the nearest in relation to vaccinia, let us take smallpox; it is well known that vaccinia running concurrently with the incubation stage of this disease renders the smallpox attack milder, and is altogether beneficial.

**Bronchopneumonia.**—"A child, E. B., aged three months, was vaccinated on October 23, 1902. The baby was not particularly robust, but her vaccination was quite justifiable. A cousin, W. H., of the same age, lived next door, the child of antivaccinators. This latter, a boy, was much stronger and more robust. Two or three days after the vaccination of E. B., both children appear to have had influenza, followed by bronchopneumonia. Under the impression that vaccination would aggravate the disease in the rather weakly baby, I was much concerned as to the issue, knowing full well that if the vaccinated infant died I should be blamed for having vaccinated her, and vaccination would be put down as the cause of her death. The pneumonic attack lasted in both children for about twelve days, and to my great relief I observed that the vaccinated baby stood the attack better than the unvaccinated one. The symptoms were not so acute, the temperature not so high, and recovery was equally satisfactory. The vaccinal process was also affected, the vesicles not so large, the areolæ not so acutely inflamed.

"The second case was that of an infant, two months old, whose mother was anxious to have him vaccinated before he was 'shortened.' On the fifth day after vaccination he developed acute capillary bronchitis, and for a day or two the baby's condition was extremely critical; that aeration of the blood was seriously interfered with was shown by several attacks of deep lividity. I fully anticipated a fatal issue by the seventh or eighth day, assuming as I did that the vaccinal process would be then fully developed and aggravate the condition. Not so, however; by that time the pneumonic process began to show signs of improvement; the vesicles were somewhat delayed in their evolution, were small in size with a small areola. I considered that as the vaccinia matured the acute symptoms of the pneumonia subsided, and so saved my patient.

**Measles and Scarlet Fever.**—"Several cases of these diseases running concurrently with vaccination were observed, with no untoward results. In one well-remembered case of measles, during a particularly malignant epidemic in which almost every case developed pneumonia as a sequela, it was observed that an infant whose vaccination ran concurrently with the development of measles, escaped pneumonia and made a better recovery than the others.

**Pertussis.**—"Of all the acute infantile diseases, none is more liable to complicate the vaccinal process than whooping-cough, the reason being that whooping-cough lasts longer than any of the others. It is interesting to observe how, with the development of vaccinia, the paroxysms of whooping-cough disappear—not that the infant's condition becomes worse, the aspect and general state improves. Of course, in a case of whooping-cough complicated by pneumonia, much the same thing happens; I have had very recently a severe case of lobular pneumonia in a child suffering from whooping-cough, and I observed very much the same thing happening; but in both conditions when convalescence is established the paroxysms return. I have had no opportunity of observing the so-called 'cures' of whooping-cough by vaccination; nevertheless, I am satisfied that the influence of vaccination on whooping-cough is decidedly beneficial.

**Influenza.**—"This, too, has a moderating influence on the vaccinal process, even though it may excite, as it has done in one well-recorded case, a latent vaccinia. A baby, A. T., aged three months, was vaccinated on December 6, 1901. Three groups of scarifications were made, two of which developed to full maturity, the pocks healed and left good-sized cicatrices. The third scarification never produced any reaction. On April 26, 1902, the baby contracted influenza from its mother. On April 30 a full-sized vesicle was observed at the very spot where the unsuccessful scarification had been made. This came to maturity with a distinctly-enlarged areola; a supernumerary vesicle was observed, showing that the areola was of more than normal reaction. The cicatrix from the delayed vesicle is more depressed, but not so foveated as the first two. The mother developed broncho-pneumonia of a severe type, the baby's attack of influenza was of a mild type and left no sequela.

**Congenital Syphilis.**—"Four babies were vaccinated at the age of about three months who were the subjects of congenital syphilis. Of course, the utmost aseptic precautions were taken, and in three of the cases mercurial treatment in the form of hydrarg. cum creta was begun at once. It was observed that during the vaccinal process the nasopharyngeal symptoms considerably subsided with the full development of the pocks, returning to their original condition at the end of a fortnight or so. In one case, the mother observed so much improvement that she considered it unnecessary to give the powders of hydrarg. cum creta with which she had been supplied. In some cases the vesicles contained large quantities of serous fluid, and, strange to say, the surrounding areola or inflammatory reaction at the base was much smaller. The pocks were slower in their development, and took longer to scab and heal up. When the scab separated a deep, sharply-cut ulcer is left with a clean base. In at least one troublesome case dressing with antiseptic care sufficed to induce a favorable healing.

**Zymotic Enteritis or Diarrhea, Tuberculosis.—Local or general.**—"These are conditions which I believe to be unfavorably influenced by vaccination. The most careful and conscientious practitioner may find himself suddenly involved during the summer season in the unpleasant position of having vaccinated a baby to find that in two or three days the child has been seized by zymotic enteritis. The suddenness of the collapse often following this state of things is very distressing, and may destroy the young life before much can be done for it. Of the deaths among the vaccinated enumerated in this paper one was of this description, dying thirteen days after vaccination, and I formed the

impression from this and other cases that zymotic enteritis, contrary to the other diseases mentioned in this paper, running concurrently with vaccination, is unfavorable.

**Tubercle.**—"I have also on record a well-defined case, aged seven months, whom I now believe, but did not at the time, to have been the subject of incipient phthisis. The child was vaccinated at his mother's request as she had been told it would improve his condition. During the vaccinal process everything went on perfectly normally and the pocks scabbed and healed within a fortnight. But very soon thereafter the tuberculous condition became more pronounced and he died four months later. Insanitary dwellings, overcrowding and filthy habits are immensely more dangerous to the recently vaccinated than the presence of such diseases as scarlet fever, measles, whooping-cough, and influenza. In small houses with large families of dirty habits with nothing cleanly in the house that either the vaccinated or vaccinator can touch, the utmost care has to be taken so that septic matter may not enter the wound. The Act of 1898 requires that insanitary houses should be reported to the medical officer of health and the vaccination postponed. This is no doubt as it should be, but the reforming zeal of the sanitary authority may be lukewarm; the time taken in putting the house in a safe sanitary condition may be so prolonged that the child may escape vaccination altogether.

**Insusceptibility.**—"The Vaccination Acts have throughout acknowledged the insusceptible, but true insusceptibility must be very rare. Four factors govern it, each of them temporary; first, and most important, potency of the lymph; secondly, the health of the individual; particularly is this the case if the child be vaccinated while in the stage of incubation of any of the exanthemata; thirdly, age; very young infants are less susceptible to successful vaccination than older children; fourthly, and perhaps to a very limited extent the experience of the vaccinator. Ill-health, particularly anemia, is a very common cause of insusceptibility for a time; let anemia be corrected, and the child will soon be successfully vaccinated. I have a case on record (M. E.) three times unsuccessfully vaccinated with active, potent L.G.B. lymph in the summer of 1902. The child was blanched and anemic, and for a time thereafter treated with iron tonics; when the anemia disappeared, the child was successfully vaccinated at the first operation.

**Eczema and Impetigo.**—"Both these conditions bring more discredit on vaccination than any disease of which I am aware. An attack of either, however far removed, is sure to be charged by the parents to vaccination. That vaccination excites dormant eczema and impetigo I have no doubt. The two following cases will illustrate this: E. R. and F. W., both the subjects of acute eczema at a very early age, were under my treatment for this complaint, and by the exhibition of Fowler's solution and other tonics made satisfactory recoveries, the skin affection disappearing completely. Two or three months later they were both vaccinated, and to my great annoyance both developed eczema very soon afterward. A. W., vaccinated on April 22, 1902, was perfectly clear when vaccinated, and remained so until after the healing of the scabs; then impetigo appeared about the neck and groins. She inoculated herself by scratching in several places, particularly on the thighs. Infection spread to other members of the family, who were not particularly cleanly. The vesicles produced by auto-inoculation in impetigo are very difficult to distinguish from vaccinia at certain stages. They scab with an areola and leave a scar. The scar is never foveated and seldom depressed. The members of this family have a romantic recollection of how vaccination spread to them all, whereas in reality it had nothing whatever to do with it.

"Let me conclude by asking a question that has often occurred to me: Granted that acute concurrent diseases modify the vaccinal process, tone down the symptoms, and delay the evolution of the pock, does it follow that in these cases it also modifies the protection which vaccination affords?"

**Security of Tenure of Office of Sanitary Officers.**—Dr. Joseph Groves, of Isle of Wight, said "when Dr. Lloyd Jones, one of the secretaries of this Section, invited me to read a paper on the security of tenure of office of sanitary officers, I replied that all which could be said on the question had been said; and Dr. Garstang, in his paper read before the annual meeting of the Incorporated Society of Medical Officers of Health in October, 1899, remarked that the reader of a paper in the State Medicine Section at the Cambridge meeting of the British Medical Association in 1880 apologized for bringing before the Association a matter which had been worn almost threadbare by discussion. But the subject is of such paramount importance to the highest interests of the community, and affects so intimately the well-being of the sanitary officer and the efficiency of his work that constant reiteration, both in season and out of season, is a pressing duty.

"Now, what are the circumstances? The country is divided up into sanitary districts administered by the rural and urban district councils and the corporations of boroughs, which are nominally supervised locally by the county councils in the areas in which they are situated, inasmuch as they (the county councils) have power to make representations to the Local Government Board. This useful provision is almost wholly neglected, I may say, while the power to withhold the moiety of his salary paid by the State, if a copy of his annual report is not in the hands of the county council within six weeks of the end of the year—a power never exercised by the Local Government Board—is being made use of to castigate and annoy the medical officer of health, and to diminish his authority and weaken his power for good in the district which he serves.

"A characteristic of the present day is a lust of notoriety, and in connection with local government in the provinces we find the same men members of several administrative bodies, thus forming a kind of official councillor class, who manipulate and control to a considerable extent local affairs. This fact may account in some measure for non-interference by the county councils with the district councils and corporations in sanitary matters, and for the persecution of medical officers of health who are not subservient to the particular members of the district councils whose aim is to dominate those bodies. That such domination is possible is due to there being very little local public opinion apart from imperial party politics and religious sectarianism, and membership of provincial councils, not excluding county councils, is falling more and more into the hands of the less-educated and of those who are prompted to occupy positions which enable them to protect their personal interests. There is, too, a certain timidity, a want of courage, a shrinking from opposition among those members of public bodies who wish to do their duty to the public and to serve their wards or parishes faithfully, and this favors the domination of the individual councillor.

"As the sanitary condition of any place in a district may directly or indirectly affect the whole district, so the sanitary state of any district may directly affect the sanitary well-being of the surrounding districts, and, indirectly, of the whole country. The Local Govern-

ment Board, therefore, representing the country generally, exercises great influence and authority in every district, an influence and authority which are increasingly necessary.

"Under the law each sanitary district must have a medical officer of health and one or more sanitary inspectors. The local authority selects these officers, and they cannot be appointed without the sanction of the Local Government Board, excepting in those rare cases in which the whole of their salaries are paid out of the local rates. As soon as they are appointed they receive from the Local Government Board—not from the local authority—their orders. These are very definite. The Public Health Act requires the medical officer of health to write a report annually on the health of his district, and the Local Government Board's orders direct him as to this report. In it, he is told, he is to describe everything which in his opinion either in the present or the future does or may, either directly or indirectly, affect the interests of the public health. He has no choice—even when obedience involves criticism of the acts, and methods of administration of his authority, which it often does. He is ordered to direct the inspector in his work, and the inspector is ordered to look to him for direction in his duties, subject to the superior authority of the sanitary authority. The relative positions of the medical officer of health and the sanitary inspector are thus accurately defined—the medical officer of health is the responsible head of the sanitary administration, and the sanitary inspector is his eye and hand so to speak.

"The terms of appointment of the sanitary officer are peculiar and most exceptional. Ordinarily in the public service, and even in private life, a man is engaged not for a definite term, unless for temporary work, but for so long as he is competent for his duties, or, as it is phrased, during good behavior. In this manner Poor-law officers of every degree are appointed, and they cannot be dismissed from office without the sanction of the Local Government Board. But outside London and Scotland the sanitary officer is appointed for a definite term—the sanitary inspector for a year, the medical officer of health with few exceptions for one, two, three, or five years. At the end of the term his appointment ceases, and the sanitary authority may proceed to select another to fill the post, and the Local Government Board, almost as a matter of course, will confirm their choice. The Board will not permit an appointment to be made without its sanction, but that having been given the Board is no longer interested in the officer; it demands only that it shall sanction the appointment of his successor. He has been dropped probably for obeying the orders of the Board, which he must obey, but that does not matter, and he has no redress whatever.

"It is evident from extracts from *Hansard* for 1872 made by Dr. Woodford that this extraordinary anomaly was not contemplated by the Legislature, whose intention it evidently was that after the first appointments, the appointments in the public health service should be permanent. Sir Michael Hicks-Beach said, in Committee on the 1872 Bill, that 'a five-years' officer, like an American President, would be afraid of displeasing those on whom his re-election depended.' And it is the opinion of Mr. Alexander MacMorran, the legal expert on the laws which regulate local government, that the Public Health Act, 1875, Section 191, provides for granting fixity of tenure. He says: 'The Local Government Board have power in cases of medical officers of health of urban and rural districts to grant fixity of tenure,' and he adds, 'it is obvious that great hardships might result from the refusal of the district council to reappoint an officer whose term had expired.'

"It is common knowledge that such great hardships have resulted in a large number of cases both to medical officers of health and sanitary inspectors from the refusal of district councils to reappoint them. Dr. Garstang, himself a victim, quoted 35 cases of medical officers of health which had come actually under his own notice who had so suffered, and these, of course, form only a small proportion of the total number. For the most part reappointment was refused because the officer had obeyed the orders of the Local Government Board; but there was one case in which the medical officer of health was also Poor-law medical officer. In performing his duties as parish doctor he had given offence, and as he could not be dismissed from his position without the consent of the Local Government Board his employers punished him by depriving him of his public health appointment.

"The extent to which this insecurity of tenure of office of the sanitary officer militates against the interests of the community and prejudices the greatest asset which the nation possesses, only the sanitary officer knows. The fear that he may not be reappointed at the end of his term of office constantly haunts him, and however much he may strive to lose sight of it, and however strenuously he may determine, whatever the consequences may be to himself, to act as a high-minded honorable gentleman, still the fact remains that moving bodies travel along the lines of least resistance, and, human nature being what it is, there is necessarily a desire to avoid friction with those placed in authority over you, and a man of generous mind makes undue allowance, perhaps, for ignorance and prejudice. He gets to feel he is the Ishmael of the twentieth century. He has offended so many people by doing his duty he is certain he will not be reappointed, and he asks himself to what good is it all. Well, I may be wrong, but it seems to me as a man of the world that the effect, and more particularly with certain temperaments, must be deterrent. Under such conditions the best possible is not obtained by the community from the sanitary officer.

"On March 8, 1895, Sir Walter Foster, the then Parliamentary Secretary of the Local Government Board, addressed a deputation in the following terms: 'The Board has arrived at a rather important decision, namely, that we consider these appointments for short periods and precarious tenure injurious to the public health. We are at one with you that men holding appointments for very limited periods cannot be expected to discharge their duties in that fearless and thorough manner which those duties require for the safety of the public, and we are anxious to encourage local authorities to give up the system of short appointments. We recognize that these offices are very delicate and difficult, as well as exceedingly responsible, and while a man is elected from year to year by a sanitary authority who may be offended by his zeal for the public health, we feel he cannot discharge his duties in the way they ought to be discharged.'

"In this utterance the Secretary of the Local Government Board—himself a medical man—eight years ago stated that it was the deliberate opinion, not of himself alone but of the Local Government Board, that precarious tenure of office was injurious to the public health, and in this opinion every person who is familiar with the question will agree. And, although the case for security of tenure of office may be permitted to rest here—for it could not be made stronger—it is but natural the sanitary officer should view the matter from his particular standpoint, for it is he who fully realizes that, as Sir Walter Foster puts it, in the discharge of duties which are very delicate and difficult as well as

exceedingly responsible, in that fearless and thorough manner which those duties require for the safety of the public, he suffers disability of a nature the like of which is unknown to any other person engaged in the public service. As Dr. Francis Vacher forcibly expressed it: 'The medical officer of health is an officer appointed *inter alia* to detect and expose the knavery of builders, to tax the rapacity of landlords, to seize and carry off the tainted goods of shopkeepers: yet these builders, landlords, and shopkeepers have absolute power over him, to strip the coat from his back and take the bread from his mouth.'

"But it is not simply that he may lose his office at the end of the term for which he was appointed, and thereby be called upon to suffer great hardships, but he has frequently to endure insult and persecution. He may be publicly disparaged and belittled and humbled and thwarted in his work, the object being to force him to resign or to bring about his non-election at the end of his term: and, if he be a strong man, he may be constantly threatened with dismissal from his post—a threat to which effect would be given much oftener but for the fear that it might be resented by the people.

"That a class of public servants who are doing a great and beneficent work, the value of which to the nation is admittedly incalculable, and for which they receive, speaking generally, altogether inadequate pecuniary remuneration, should be permitted to pursue that work under conditions which are inimical to it, and that they should be allowed to be penalized and persecuted, and to suffer hardships and indignities because they do their best to fulfil their obligations and obey the law, passes comprehension.

"Why is it? Undoubtedly the Local Government Board and the Government of the day are primarily responsible, but it is difficult to arrive at the considerations which influence the permanent officials. Since 1895, when Sir Walter Foster gave expression to the views of the Board, which were very much in agreement with those of the health officer, its President has steadily declined to receive any deputation on the subject, and it is only from opinions expressed by individuals from time to time that any idea can be formed.

"Another reason I have heard advanced is that sanitary officers would not do their work so well if the tenure of their offices were secure. This would be a valid argument were it true, but some medical officers of health hold permanent appointments, and no one can say they are worked less efficiently on that account; indeed, the effect must be the very opposite. The Poor-law officers of every degree are not less efficient because they cannot be dismissed without the consent of the Local Government Board.

"I have been told that it is in the minds of some of the permanent staff of the Local Government Board that in the course of evolution of the public-health service great changes may be made, such as have taken place in Scotland, and that, if the appointment of the sanitary officers were permanent, they would have to be compensated for loss of office. One can only hope as a citizen of a wealthy kingdom, which claims to be in the van of civilization, it is not true. It would be contemptible in the extreme if, after the sanitary districts were got into good order, the men who had done the work at so much cost to themselves should be simply sent about their business.

"But whatever the cause or the combination of causes which permit the continuation of an anomaly which occasions serious detriment to the interests of the public health, and is a gross injustice to the sanitary officer, I believe the medical officers of health have the whole-hearted sympathy of those of our profession who understand the question. That we have the very practical sympathy of the British Medical Association—the great representative body of the profession—is certain, for they are doing all they know, by promoting a Bill in Parliament at some expense, and by seeking an interview with the President of the Local Government Board. During the preparation of this Bill it was a graceful act of the Incorporated Society of Medical Officers of Health to request the Council of the British Medical Association to include the sanitary inspectors in its provisions. In my opinion it was right and just, for the sanitary inspectors have suffered as we have done, often because they were loyal to their orders and to us; and it has its advantages to them and to us, for it has united our forces by the withdrawal of their Bill.

"That the Bill will pass into law is not probable without the assistance of the Government, and that assistance is not likely to be rendered without the sanction of the permanent officials of the Local Government Board. In the meantime, by the kindness of our good friend, Sir Francis Powell, and of those who assist him by backing the Bill, we are keeping before the public the injury inflicted upon the public health and the disabilities of the sanitary officer.

"We of the British Medical Association have no choice as good citizens but to continue the agitation by pressing the subject upon the attention of members of Parliament in our respective districts, and upon all those who take interest in public affairs or who can influence public opinion. And in time I have no doubt, if we are true to our responsibilities, we shall succeed in removing not only a burden from our own shoulders, but a menace to the highest interests of our neighbors and that which is a great and serious reproach to England."

**The Appointment of a Minister of Public Health.**—Dr. Frank G. Bushnell, of Plymouth, said "Members of the medical profession including many medical officers of health, the British and Canadian Medical Associations in council, the Sanitary Institute of Public Health, the Manchester and Salford Sanitary Association, the Imperial Vaccination League, the County Council West Riding of Yorkshire, the Institute of Sanitary Engineers, the Workmen's National Housing Association, the Childhood Society, members of Parliament and Medical Societies have considered and expressed approval of the appointment of a Minister of Public Health.

"Such a Minister would act as a leader. The value of a leader is exemplified in science, statecraft, religion, war, commerce, and indeed in every sphere of human activity. The individual leads the way, others follow in his footsteps; for example, Kaiser Wilhelm, M. Pasteur, Lord Lister, Mr. Joseph Chamberlain, 'General' Booth. The importance of the individual and human factor is brought home in Napoleon's famous saying, 'Men are nothing, the man is everything.'

"We have illustrations of the abolition of disease consequent on the adoption of measures suggested by preventive medicine. With the appointment of a Minister this may be expected to occur more and more. For example: The abolition of smallpox in Germany; the abolition of rabies in England: the diminution of sepsis by 'Listerism;' the disappearance of leprosy with improved sanitation. Such are mere reminiscences of the possibilities of preventive medicine in the abolition of disease.

"Zymotic and tuberculous diseases are recognized as largely preventable. The Sixty-second Report of the Registrar-General of the United Kingdom for 1899 gives the deaths from zymotic diseases as 89,235, or 2,811 per million of population. Tuberculous diseases

destroyed 60.659, or 10.4 per cent. of deaths from all causes, 1,911 per million of the total population thus arose. Alcoholism caused the death of 2,871, or 112 per million living among males and 70 among females. Cancer and malignant disease destroyed 26,325 persons, or 829 per million of all ages and both sexes. As to the infant mortality, 163 infants under one year of age died in 1899 in every 1,000 of the population in England and Wales. It has increased from 149 in 1871-80, and this implies heavier incidence of disease in infants, with ill-effects in after-life. There were 82,103 deaths in lunatic and idiot asylums, or 14.1 per cent. of the total deaths in England and Wales.

"It is hoped that such a list of mortality figures will set men thinking. It cannot be accepted from any point of view as the ideal of the art of citizen making. Without being convinced that the national physique is degenerating, as has been argued from the reports of the Inspector-General of Recruiting—from the decline in the birth-rate, from the increase in the death-rate of infants under 1 year old, and from statements made by members of the Royal Commission on Physical Condition in Scotch Schools, yet the most optimistic of us must be impressed with the fact that the health and physique of other countries is said to be markedly improving.

"It is claimed by those skilled in vital statistics that one-third of the deaths annually registered are dependent on causes which proper administration of sanitary measures could remove. It is said that the appointment of another Minister would lessen the individual weight of those that exist. The withdrawal of highly specialized duties from overworked departmental heads cannot be construed into a loss of prestige. It is merely a development in the natural order of affairs. The superintendence of the health of millions cannot be practicable in addition to other vast and onerous duties.

"Just as—or even more so than—a municipality and county appoints its medical officer, so should the nation. It cannot expect to be served for ever by other officers, however able and strenuous they are.

"Again, it is said that the effective discharge of public health regulations must eventually devolve on local authorities. True, but a Minister would act as the best incentive to proper sanitary progress by many. A superfluity of Ministers is said to exist already. Surely if many have been found good and necessary in the past, we must rely on our experience and appoint another, if indicated.

"Again, I am asked if existing arrangements are really sufficient. To this I would answer by a question. Are the preventable diseases diminishing as instinct and science tell us they might? Do medical officers of health of districts of schools or of troops believe that the interests of health are thoroughly guarded? As for a Minister restraining progress, I am sure in the long run the gain to the interests of health by a leader, especially a trained one, would far outbalance 'official' tendencies in its narrow sense. Further, looking back on those who have guided us in other matters in the past, can we say from a broad basis of judgment that we should have been better without their services?

"It is thought by some that the formation of a ministry would detach sanitary administration from other departments of local government and cause friction with the Local Government Office. However, the appointment of a Minister of Education has, curiously enough, been coincident with the actual unification of education and local government. It may be concluded that it is possible for a Ministry of Health and Local Government Office to cooperate harmoniously, the more so perhaps when we remember that the administration of the public health is combined and included in other countries in State offices of Agriculture, Navy, Education, and Police.

The question of expense is met to a certain extent by the fact that in a new Health Ministry certain officials are already existent but scattered among many departments; and also that saving of money results from prevention of disease, and in any case cannot be judged from the point of view of £ s. d. The mover of a resolution in favor of a Ministry of Commerce at the recent annual meeting of the Associated Chambers of Commerce, gave it as his opinion that commerce is the foundation not only of the prosperity of the people but of the empire itself. Another speaker said that it was obvious that commerce was its very life. This is indeed an erroneous view. What position would this country have held without its vigorous health, its bodily mental and moral 'grit' in the past? Lord Beaconsfield went so far as to say that 'the health of the people is really the foundation upon which all their happiness and all their power as a nation depend . . . but if the population of that country is stationary, or yearly diminishes in stature and strength, that country is ultimately doomed.' What does Ruskin say? 'There is no wealth but life.'

"The apathetic who expect the world to stand still in its course and present arrangements to suffice must remember that there are numbers who exist under conditions of 'sanitary injustice' at present, and without a leader they are helpless.

"In the Minister many would see the embodiment of a principle the importance of which is absolute but unrecognized frequently. It is that, whatever the demands of complicated modern life make upon us, whether in crowded communities or rural districts, on land and on sea, in this country or in our great tropical colonies, the natural or physiological laws of health must be obeyed or exact their toll inevitably. The Minister would regulate the balance between the forces of Nature and civilization. The Minister would add weight to the recommendations of local sanitary authorities, would assist those in need of help, would stimulate the apathetic, and would remove such limitations as unduly bound others, would be compelling to those who wilfully neglect their duty. Unnecessary interference would be avoided. The guiding light which would steer the Government barque between the rocks of neglect and interference would be the health requirements of the people based on scientific medicine.

"The value of the work done by voluntary effort in this country is, and will be, enormous. This is right. It is said that every great sanitary improvement has been initiated by voluntary or local action, and this is truth.

"The Local Government Board was established in 1871 to concentrate in one department of the Government the supervision of the laws relating to the public health, and the relief of the poor and local government. Its constitution is probably familiar to you, and it may be remembered that it originated partly on the recommendation of the Royal Sanitary Commission (1869-71), who expressed the opinion that, if such a Ministry were established, separate secretariates—one for public health and one for the relief of the poor, would be found necessary. This was not carried out, however, but all administration was concentrated in the hands of one secretariat, and was in fact a continuance of the former Poor-law Office.

"The Royal Commissioners had expressed or implied that the new authority would be a 'motive power' of no mean degree for promoting sanitary progress. It is impossible to avoid a comparison of such a stimulating

plan of action with the policy of the Board in 1888, when it desired to transfer to county councils all the powers which it now has under the Public Health Act of enforcing on defaulting district authorities the performance of their sanitary duties. In 1903 there are yet more county councils without than those with medical officers of health, I learn. It was obviously a premature effort at decentralization. The powers and duties of the Board are those of the Poor-law Board with those of the Privy Council. All the powers and duties of the Home Office in relation to public health, drainage and sanitary measures, local government, local returns, and local taxation. The growth of its duties is steady and continuous. It has legislative powers of making rules, regulations, and orders, and confirming by-laws. Its administrative control varies considerably; over Poor-law matters it is complete; over municipalities the Board has no direct control. Over sanitary authorities that Board has considerable power; it can force them to carry out sanitary measures to its satisfaction. Other powers have been conferred upon it, and it has certain obligations. In 1888 it received the central control of the county councils, an omen of future expansion as the tide sets in towards local government *pari passu*.

"The expanded Medical Department of the Board, the General Register Office, and officers from other departments would well form a basis of the Ministry. Associated with it should be a consulting body of representative or eminent members of the medical profession, for example, the Presidents of the Royal Colleges, a medical officer of health of schools, of factories, of Poor-law patients, prisons, navy and army. A veterinary surgeon, statisticians as the registrar-generals, an alienist, a pathologist, a sanitary engineer, and architect would be most suitable consultants.

"Education would be the most powerful engine that a Minister could exert in developing that 'health conscience,' which is desired in Scotland. The present system is too slow a process in this country, and the most effective way to protect the interests of the general public is to create a strong central department with effective control of local departments. It appears that local authorities when combined overawe even Parliament itself, and Parliament must be supreme.

"In a few words, the Ministry would deal with the records of disease, vaccination and revaccination, with outbreaks of epidemics and infectious sickness, with the regulation of injurious trades and industries in relation to health, with the prevention of filth, and with the infant mortality. Hospitals of all kinds, open spaces, gymnasia, swimming baths would all be advised upon; attention would be drawn to deficiencies; the adulteration of food and drugs, analysis of water, etc., would be dealt with; diseases communicable from animals to man, chemical and pathological research as to the causation and prevention of disease of mind and body at home and in our colonies; bacteriological investigations of human and animal morbid conditions, etc., would be supervised.

"Education in hygiene would be studied and inculcated as of paramount importance. The returns of the coroners' courts and meteorological observations would be collected. The Home Office might see fit to part with the supervision of the health of workers, prisoners, police, and lunatics.

"The Veterinary Department of the Privy Council would well be associated with the Ministry. The Minister would perhaps serve the interest of the public health best if he were not liable to change with every Government. He would be an adviser rather than a participator in the fierce and often unnecessary party strife of politics. Indeed, he might be definitely cut off from the collective responsibility of the Cabinet and be only summoned to the meetings of the Cabinet which had to do with his department. It is in the power of the Sovereign to summon any privy councillor to any Cabinet for any particular purpose and there is no obvious reason why such a course should not be adopted in this case.

"In conclusion, I may say that a list of eminent men could be given who advocate the creation of a Ministry of Health. It is difficult, with the present figures at my disposal from other countries, to compare satisfactorily the various National Health Departments, but I may say that Canada and the United States are moving toward such a separate office; Germany, France, and Italy may be said to have already compulsory physical education in their systems of military training.

"If I can arrest the attention of this meeting on the central idea of the necessity for Ministers of Public Health presiding over a national organization I am well content. I beg to move 'That this meeting is of the firm opinion that a Minister of Public Health would possess great potentialities for improving the national health, and would eventually benefit it largely. It is further of the opinion that the Council of the British Medical Association should advise that a Government inquiry be made into the advisability of uniting the public health work of various departments into one Ministry under the control of a Cabinet Minister.'"

Mr. Herbert Jones, of Hereford, sympathized with the object which Dr. Bushnell had in view, but maintained that there was already a Minister of Public Health in the President of the Local Government Board. A fatal flaw in Dr. Bushnell's proposal lay in his suggestion that the Minister of Public Health should hold office irrespective of change of Government. The discussion of the subject was opportune in view of the probable introduction within a short time of a Public Health Bill for England and Wales.

Mr. H. H. Tidswell, of Chester, said that in the interests of public health he would like to see increased powers given to medical officers of health for the purpose of daily inspection of houses in every town, with the view of preventing the spread of infectious diseases and for the purpose of warning those parents who persistently neglected the health of their children. To carry out this system the medical officer of health should have the power to appoint the general practitioners of different districts to carry out this work, and to pay them according to the work done. It was desirable to make the experience and knowledge of the general practitioner available for the public health service, but not gratuitously as it was at present.

Dr. Joseph Groves, of Isle of Wight, said the difficulty was that the Treasury did not grant the Local Government Board sufficient funds to enable it to employ more assistance, and consequently there was always a block of work. The medical department was only one of the departments of the Local Government Board, and it would appear that the reports of this department were considered by the permanent secretaries, with the assistance of the medical officer if considered necessary. He believed that at the moment the greatest amount of good to the public health would be found in security of tenure of office to sanitary officers.

Mr. H. D'Arcy Ellis, of Stourbridge, did not see what advantage was to be gained by the appointment of a Minister of Public Health. He believed he had the honor of being the first medical officer of health who obtained security of tenure. He did not know that the security which he now had made any difference to the good relations existing between himself and the local council; but he did feel that more backing up was required, somewhat on the lines on which he believed the

Factory Department was now administered under Dr. Whitelegge, and carried out under the medical inspection of Dr. Legge. As to educating public opinion, he believed that the public were becoming much more alive to the necessity of good sanitary administration, and there was growing up a healthy public opinion which would bear good fruit; he was quite sure that in his own district much more interest was being taken in sanitary questions. Of course, his reports did sometimes bring him and his council to close quarters, especially when inquiries were made from the central department, but these matters were always adjusted by the usual stereotyped reply, and did not always end as satisfactorily as the medical officer of health might desire.

**Physical Degeneration in Children of the Working Classes: An Inquiry Into Its Causes and Suggestions for Its Remedy.**—Prof. Herbert H. Tidswell, of Chester, asked "What is meant by physical degeneration? It denotes a condition of mind and body below the normal standard of development—deficient in vigor, activity, and endurance. The object of my paper is to draw attention to certain psychological influences which to my mind are responsible for the nervous restlessness and waywardness so characteristic of the children attending the schools under the Education Act. It is not my intention to dwell on such well-known factors of disease as starvation, exposure to cold, improper feeding, want of rest, want of fresh air and sunshine, and insanitary dwellings. I think no one will deny that the standard of health among school children in our large towns is lower than it ought to be. I will not be so rash as to assert that it is lower than it used to be; but it certainly is not so high as it ought to be, considering the advances in all departments of sanitary legislation and the improvements in hospitals and dispensaries for the free treatment of the poor. It is evident to my mind, as the result of my investigations, that there is some factor having a bad influence on the health of children which did not exist before the new system of education came in force. The children of the working classes of the present day commence school attendance too young. The period of school attendance is much longer and the course of studies much harder than it was under the old system. The rules of the new system put burdens on the teachers and pupils not easy to be borne with equanimity, while the system of cram is turning children into talking machines and injuring their reasoning powers.

"These are powerful factors in producing cerebral congestion. The mind of a child is remarkably sensitive. Harshness and severity, either on the part of a teacher or parent, will destroy the happiness of a child's life, disturb the appetite and digestion, and drive away sleep. A child's anxiety to please a parent or teacher, if unsuccessful or not appreciated, will have the same effect. I know from personal experience that fear may have a paralyzing effect on the mental faculties. In my early school days I had a severe master; one day he flew into a temper, and threatened to cane me because I was slow at mental arithmetic. My difficulty was to add 8 and 1 together, but so long as he stood in front of me with his cane I was too frightened to utter a word. I have seen several cases of chorea occur in girls as the result of school worry. It is my opinion that many cases of hysteria and other nervous maladies in young women of ovarian and uterine origin may be traced to over mental strain during school life.

"To return to children. It is an axiom that the physiognomy is a certain index of the state of the feelings, for example, when a child is happy and content, his face will show his state of mind. When he is irritable, tired, or overworked, the child's face will bear a pained, weary, haggard, or careworn expression. It is natural to assume that boys and girls are usually glad when lessons are over and they can go and play or return home for dinner.

"I have often stood still outside schools to note the expressions of children coming out of school. A few only had a look of joy and happiness. The majority had a sad, careworn, haggard look, suggestive of mental strain. The behavior of some was so unnatural as to lead me to suppose their brains were highly irritable. I saw one boy take his overcoat, fold it up, and then kick it along the pavement. Did this indicate a healthy state of mind? When I was called upon to treat delicate or nervous children I invariably ordered rest from school for several months which was usually followed by improvement.

"Parents have frequently complained of the severity of the school regulations and occasionally of the severity of the teachers. Children's brains are delicate organs and require gentler treatment than they often receive at the hands of their teachers. The cram system of the present day is both demoralizing and degrading and is calculated to render the judgment unstable and capricious and to interfere seriously with the mental equilibrium. The development of the body is seriously retarded by a morbid condition of the cerebrospinal system. In some schools it is customary to punish children who are late for school by a stroke of the cane on the palm of the hand. I have never seen this punishment inflicted, but I imagine it is greatly dreaded as children take great pains to be in time. I think corporal punishment should be absolutely forbidden in school.

"In some towns parents have difficulty in getting permission from the teachers for their children to remain at home in cases of sudden illness; many parents are unable to afford a doctor's fee, and hence cannot obtain a medical certificate. They are often afraid to allow a child to remain at home when ill. I recently met with a sad case of this nature. A poor woman in charge of a little grandson kept him at home from school for a day or two, as he had a violent cough and was very ill. The school attendance officer called and inquired why the boy had not been to school. He was told the reason, but did not think it satisfactory, so he gave strict orders for the boy to return to school. The boy was too frightened to disobey, and went to school, but almost fainted in the effort of getting there, while his cough disturbed the whole class. As his illness became worse the grandmother got alarmed and sent for me. I went to the house at once, and found the boy very ill in advanced consumption; he was treated with the greatest care, but he got gradually worse, and death terminated his sufferings in the course of a few weeks. In another case a boy was attending school for a week while suffering from scarlet fever.

"I think I have said enough to prove that the medical aspect of our system of national education is far from perfect, and that it is probably a powerful factor among others in the lowering of the standard of national physique—mental and bodily. Few men have the same opportunities as general practitioners of studying child life under the Education Act; they alone and the parents can trace the connection between mental strain, nervous instability, and disease.

**Suggestions for a Remedy.**—(1) "If possible remove the cause of mental strain and abolish the cram system. (2) Let all schools be under systematic medical inspection, let a medical officer be attached to each school, who shall inspect each class as it assembles to detect infectious or other diseases in the early stage, who shall examine the eyesight, the hearing, and general condition of each child and keep a report of the same.

who shall visit any pupil at home in case of sudden illness and give certificate to same. A measure of this kind would entail cost, but in the end it would be true economy, it would save a vast amount of suffering and ill-health, and would help to raise the standard of national health.

"In conclusion, it may not be amiss to point out that the object of education, before the introduction of the Education Act, was to train boys and girls for their duties in that station of life to which it had pleased God to call them. Whether that is the object under the present system is a question I will not presume to answer. My last words are an earnest appeal to parents. Remember the words of our great poet, Lord Tennyson. 'Self-reverence, self-knowledge, self-control. These three alone, lead life to sovereign power.' Teach your children this lesson, and they will bless you in after-years."

Dr. Dawson Williams thought that "some definition of terms was needed. What was meant by the term 'physical degeneration?' Did it mean a progressive degeneration of the race? If so, there was not, so far as he was aware, any statistical evidence that the amount and degree of degeneration in the population was increasing. Theoretically, the proposition involved the assumption that acquired characteristics could be transmitted, and those who accepted the doctrine of Weismann would find great difficulty in accepting that assumption. The practical question appeared to be whether the factors which tended to prevent adequate physical development could be removed? Whether these factors were more operative at the present time than fifty years ago might be an interesting question from the historical point of view. He hoped that the inquiry into the causes of the defective physical development which existed in many populous districts would not be mixed up with the question of the causes of the decline in the birth-rate. The two matters were distinct. The steps to be taken to safeguard life from the time of conception formed a field of work sufficiently wide, and attention should be given to safeguarding the health of the mother during pregnancy. The food supply of the poorer classes in populous districts differed from the supply thirty or forty years ago in respect particularly of the large increase in the use of preserved foods. Whether the use of starchy foods for infants had increased or not it was undoubtedly excessive, and the condition in which milk reached the infants of the poorer classes was another factor which deserved remedy. He believed that the defects in the diet of infancy and youth caused a condition of defective nutrition which produced not only imperfect physical development, but imperfect or retarded cerebral development, which was the cause of what was called over-pressure."

Mr. J. M. Mackenzie, of Kirkby-in-Ashfield, believed that physical degeneration was both acquired and transmitted. School children who left school very healthy soon degenerated when occupied in unhealthy employment. Physical training was greatly needed. Children's homes should be improved, and they should have more recreation and better food. The marriage system must also be looked to. People were allowed to marry who would always produce a stunted and degenerate race.

Dr. John Strachan, of Dollar, referred to the great need of medical guidance in the matter of school procedure, holding that it should be the duty of the profession to safeguard the children in regard to the conditions of health of which schoolmasters were not required to have any knowledge. He thought that long confinement in school and at school work, amounting often to eight or nine hours of sedentary work, had a great tendency to deterioration of the physical condition and tendency to disease; and that the effect upon the nervous system of punishment and other terrorisms imposed upon children in connection with school lessons interfered with sleep and tended to injure the mind.

(To be Continued.)

## BOOK REVIEWS.

The Medical and Surgical Uses of Electricity. Including the X-Ray, Finsen Light, Vibratory Therapeutics, and High-frequency Currents. By A. D. Rockwell, A.M., M.D. New Edition. E. B. Treat & Co., New York.

The classical work of Beard and Rockwell appears in an entirely new and modern form in this new edition of Rockwell's, and to it are added a number of the modern applications of physical therapeutic measures.

The work has been received by the profession as one of the oldest and best, and we can add but little to former opinions expressed in the News.

The present edition brings the subject of the medical uses of electricity thoroughly to date.

Felix. A novel. By Robert Hitchens. Frederick A. Stokes Co., New York.

This is a fascinating tale of a phase of English life in which the development of a young boy of eighteen years of age is told with more than usual brilliancy and greater graphic truth than is usual in works of this type. But that is not the main feature of the book that renders it of absorbing interest to the physician. It is, in addition, a most thorough and careful study of morphinism as found in two women. The description, while in certain regards slightly overdrawn, is so well done that we venture to say that there is no work of fiction that deals with this question so well and thoroughly as this.

As a novel the work is absorbing, almost fascinating. As a study of the morphine habit it is entitled to scientific praise, and we recommend it to our readers most cordially.

The Autobiography of a Thief. Recorded by Hutchins Hapgood, author of Spirit of the Ghetto, etc. Fox, Duffield & Co., New York.

Accurate studies in criminology have heretofore been more conspicuous by their absence than by their presence in English literature. Josiah Flynt has happily laid the foundation of a sound literary handling in this field and many imitators have commenced to follow in his train. The present volume, however, should not be considered in the light of an imitation. It is, we believe, a truthful account of an ex-convict's life. A convict who, having been trained along other lines, might have been a useful citizen. As it was, he became successively a pickpocket, a porch climber, a robber, and a professional thief, who spent more than one-half of his life in prison. Apart from certain minor anachronisms the story is well told. The vernacular is carefully reproduced and the human side of the thief's life are brought out in an eminently sane and competent manner.

While it is too early to prophesy the reform of many of the characters of the under world, it is essential that as students of criminology we should carefully collect our facts and not attempt systems of reform or punishment on the metaphysical hypotheses that have heretofore characterized much of our so-called knowledge of criminal characters.

We cordially commend this work to all those interested in the study of this type of individuals.

### THE REDUCTION IN THE INFANT MORTALITY IN THE CITY OF NEW YORK AND THE AGENCIES WHICH HAVE BEEN INSTRUMENTAL IN BRINGING IT ABOUT.*

BY ROWLAND G. FREEMAN, M.D.,

OF NEW YORK;

LECTURER ON PEDIATRICS, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL SCHOOL; ATTENDING PHYSICIAN FOUNDLING HOSPITAL; NURSERY AND CHILD'S HOSPITAL, NEW YORK.

THE infant mortality of any community is in a general way a good indication of the health of that community. A high general mortality is usually an evidence of a very high infant mortality. The infant mortality in all large communities is shockingly high, since from one-tenth to one-third of all infants die during the first year. That such an infant mortality is absolutely unnecessary is proven by the fact, that of babies born with good surroundings and properly cared for not one in a hundred die during the first year. It is manifestly impossible to give the tenement house babies all the care and luxuries that may be enjoyed by the wealthy but this is not necessary in order that they may be under such conditions as will materially reduce their death-rate.

TABLE NO. 1.

INFANT MORTALITY. DEATHS IN FIRST YEAR PER THOUSAND INFANTS.

| | |
|---|---|
| Norway and Sweden | 106.157 |
| England | 154. |
| France | 169. |
| Prussia | 217. |
| Italy | 220. |
| Hungary and Austria | 254.258 |
| Bavaria and Wurtemburg | 317.329 |
| United States in 1900 | 159. |
| New York City in 1902 | 158. |

In European countries, as is shown by Table No. 1, the infant mortality varies from 106 to 329 a thousand. In the United States according to the last census it was 159.3, while the cities of the country showed a mortality of 184.7. This was a marked improvement over the census of ten years before, 1890, since the total infant mortality of the country had decreased from 246.30 to 159.3 and that of cities from 303.86 to 184.7. In New York State the mortality in 1900 was 159, about the same as for the country and materially more than that of the cities of the United States. The mortality of colored infants is more than twice that of white infants. Thus in the last census it was 397.2 in cities as compared with 180.4 for white children.

The infant mortality of New York City has been very materially reduced in the past twelve years as is shown by Chart No. 1. The mortality from summer diarrhea in 1902 having been less than half what it was in 1892. Ten years ago the infant mortality of New York City was higher than that of many European countries while now our mortality of 158 is lower than that of most European countries and indeed than that of many smaller cities of this State, as shown by Table No. 2.

In view of this striking reduction in our infant mortality it is important that we should if possible ascertain what these agencies are that have brought it about. It may be asked, is the decline in mortality during the past ten years simply a part of a general decline which has been going on previously? I have not been able to get figures of the infant mortality of New York City before 1891, but have prepared a chart (No. 2) of the general mortality which shows no material decline in mortality between 1883 and 1891, so that this decline is due to influences operative during the past ten years.

An analysis of the figures from which the dotted, dashed and solid lines on Chart No. 1 were constructed, shows that the total infant mortality, represented by the solid line, has decreased from 242 to 158, or about two-thirds, while the deaths during June, July, August and September, represented by the dotted line, have decreased to somewhat more than half, thus showing a much greater reduction than the general infant mortality. The third class of deaths, from infantile diarrhea in summer, represented by the dashed line, however, shows the greatest diminution, the present death-rate being just one-half that of 1901 or 1902. The influences that have acted on the general infant mortality have acted largely through the mortality from summer diarrhea.

The causes of infant mortality and especially of summer diarrhea may be classified as: (1) Heat and humidity; (2) defective feeding; (3) bad surroundings. The increase in infant mortality in the summer over that in the cooler months is also shown well in the chart showing the infant mortality by months (No. 3). Thus with the beginning of warm weather in June the mortality increases, reaching its height in July and then rapidly falling in August. On studying

* Read before New York County Medical Society, April, 1903.

this chart we are likely to believe that this increased mortality is due to heat and humidity, but why do so few deaths occur in August when

ered and furnished to me through the courtesy of the Department of Health, shows graphically, daily observations of the number of

Chart No. 4, constructed from data gath-

deaths from diarrhea, in New York City in children under two years (solid), the temperature (dotted), and humidity (dashed), during June,

July, August and September, 1902. There is evidently some relation shown between the dotted line, representing temperature, and the solid line, representing deaths, but it is not constant. It should, however, be noted that New York was singularly free from very hot weather during that season. No physician who has visited regularly, in summer, the wards of the babies' hospitals can doubt that heat and humidity have a serious effect on sick babies, a hot summer day usually showing a rise in the temperatures accompanied by an exacerbation of symptoms. While this is an important factor, there is a far more important factor in the food of the babies. Heat and humidity do the babies more harm indirectly by spoiling their food than by direct action on the child itself. This is well shown by the fact that babies that are given nothing but breast milk rarely suffer from diarrhea. It is also well indicated by the chart showing the mortality of certain European countries. For instance, where the babies are breast-fed, as in Norway and Sweden, the mortality is very low, while in Bavaria and Würtemberg, where they are mostly bottle-fed, the mortality is three times as high. Moreover, the babies of New York City fed on the Straus pasteurized milk have been found to do much better than those fed on ordinary milk. The third cause of infant mortality, bad surroundings, is significant. A hot, humid day out of doors is bad enough, but in the crowded tenements, with a fire burning in the kitchen of each apartment, the prostrating effect is much greater.

In view of the striking reduction in infant mortality, which has been referred to above and having considered these influences which contribute to the mortality, namely, heat and humidity, defective feeding and bad surroundings, we may now consider the various agencies which have been instrumental in reducing this mortality.

In considering these agencies we may assume that those which furnish to bottle-fed babies a better food than they formerly had are most important while those which improve the environments of the babies and give them fresh air are important contributory factors. In order to bring together these agencies in graphic form I have arranged a chart (No. 1), at the top of which I have noted the highest temperature of the summer as well as the mean temperature for July and August, and it is noteworthy that in these steadily descending mortality curves the abrupt rises are always associated with hot summers. Beneath this large chart I have noted the dates of the last three city administrations. The Strong administration by reforms in street clean-

ing, by an intelligent and energetic administration of the Health Deparment and by inaugurating a system of small parks, play grounds and recreation piers did much to secure the diminution in the death-rate during that administration and during the first two years of the Van Wyck administration.

The most important factor in reducing the infant mortality in New York is evidently not a local influence but one that applies throughout the country, for we have already seen that the infant mortality of the United States has been reduced during the past ten years in the same manner as that of New York. Thus, also, the report of the Board of Health of New Jersey for 1902 shows a marked falling off in the mortality of children under five years from 81.82 per thousand in 1892 to 40.23 in 1898. This reduction was evidently due to the sterilization and pasteurization of milk. It was at about the time that this diminution in infant mortality began that sterilization of milk in the tenements of New York City was generally adopted. So general has it now become that the inspectors of the Rockefeller Institute, when seeking statistics concerning the effect of different sorts of food on the health of babies in the tenements in summer, were able to find scarcely any that were fed on raw milk.

A definite example of the diminution in mortality from pasteurization of milk occurred in the Infants' Hospital on Randall's Island where the mortality in 1897 with raw milk was 44.36 while in 1898 with pasteurized milk it was 19.80. The importance of this factor cannot be too strongly emphasized at the present time when many physicians seem inclined to revert to raw milk.

The control of the city milk supply by the Board of Health may well be cited as an important factor in reducing infant mortality. Although the Board of Health had been active previously in its endeavor to secure good milk its exertions became much more vigorous in 1892, from which date a steady decline in the death rate ensued. It is also interesting to note that in 1899, 1900 and 1901, when there were fewer prosecutions for violations of the ordinances respecting pure milk, a slight increase in the death-rate is recorded while with largely increased activity in 1902, when there were 722 arrests and prosecutions of milk dealers, as compared with 464 in 1901, 460 in 1900, 193 in 1899, there was a diminution in the death-rate to the lowest point in the history of the city. I do not hold that these facts stand to each other absolutely in the relation of cause and effect but they afford at least a very interesting coincidence.

A second important agency in securing suitable nutriment to the bottle-fed babies is the Straus Milk Charity. Organized in 1893, the year in which the decline in death-rate began, with an output of 30,000 bottles it supplied in 1894, 300,000 bottles, in 1895, 600,000 bottles. The output then remained about the same until last year when milk certified by the Milk Commission of this Society was used by them and the demand reached 1,200,000 bottles, this enormous increase in distribution being accompanied by a diminution in infant mortality. New York City certainly owes to Nathan Straus a great debt of gratitude for inaugurating and carrying out, at his own expense, this most valuable aid to its tenement house babies. In connection with this may be mentioned the various commissions of medical men formed to improve the milk supply, which, by placing certain dairies under hygienic conditions, furnished an example to the ordinary dairyman and set a standard of pure milk.

The next agency in importance in the reduction of infant mortality seems to me the work of the St. John's Guild. This organization supports admirably equipped hospital-boats which make trips down the bay to the south shore of Staten Island where an excellent hospital receives the very sick cases. It was inaugurated in 1875 and furnished then three trips a week, it has, however, steadily extended its work and now supplies 12 trips a week, having two boats in service. This society thus takes away from 13,000 to 18,000 babies every summer and these are carefully fed and bathed during the trips. It is noticeable that the summer of 1899 when its activities were doubled by the services of a second hospital barge, the infant mortality dropped from 262 to 210 a thousand.

This is but one but by far the most complete and extensive of many organizations working in New York City with much the same end in view, such as the Association for Improving the Condition of the Poor, The Children's Aid Society, The Sanitarium for Hebrew Children and the *Tribune* Fresh Air Fund. Altogether probably 35,000 infants are thus taken out of New York City during the hot months of July and August.

A factor of no little importance in diminishing our infant mortality was the appointment by Mayor Strong of Col. Waring as Street Cleaning Commissioner in 1895. He not only cleaned the streets but showed how it should be done. The prompt removal of garbage and refuse under the Strong administration aided in keeping the tenement districts healthful.

The development of diphtheria antitoxin in 1893 and its manufacture and free distribution among the poor by our Board of Health since 1895 which has reduced the mortality from this disease from 40 per cent. to 10 per cent., has diminished infant mortality, especially in the hospitals for infants where prophylactic injections of antitoxin are used.

The gradual paving of our streets with asphalt in place of the stone blocks has made them easier to keep clean and thus added to the healthfulness of the city. This was begun on an extensive scale in 1890 and in 1892 a number of streets on the lower East side were thus improved. During the last year of the Strong adminstration 1897, more streets were asphalted than ever before. Two-thirds of our asphalt pavements have been laid in the past five years.

The opening up of small parks in the crowded

districts, by the destruction of tenements, began with the Mulberry Bend Park in 1897, the opening of playgrounds for children, through the efforts of the Outdoor Recreation League, began in 1898 and the establishing of the six Recreation Piers beginning with that at East Third Street in 1898, have all helped the babies to obtain fresh and cool air during the summer.

One more influence, the condition of the tenements, is an important one. Overcrowding has for many years been controlled by the Health Department but it was not until the Gilder Tenement House Commission of 1894 began its labors that the evil conditions were generally appreciated. Soon the results of our new tenement house laws and their enforcement by the Tenement House Department should be accompanied by a still lower infant mortality.

In conclusion the following summary may be presented: (1) The infant mortality of all countries is shockingly high and this is shown to be unnecessary by the fact that infants that are well cared for show a very low mortality. (2) The influences that contribute to the high mortality are defective feeding, the active cause, and heat and humidity and bad surroundings as contributory causes. (3) There has been a marked decline in infant mortality during the last ten years in the United States and especially in New York City, due, for the most part, to the decline in mortality from summer diarrhea. (4) This striking decline in infant mortality is due to many agencies. The general adoption of pasteurization and sterilization of milk for infant feeding is by far the most important of these and applies to New York City and the whole of the United States. Other agencies in New York City are the improved city administration, the milk inspection of the Department of Health, the Straus Milk Charity, the fresh air work of St. John's Guild and similar charities, cleaner streets and asphalt pavements, the new small parks, playgrounds and recreation piers, the improved tenements and the use of diphtheria antitoxin.

## NEGLECTED PROPHYLACTIC MEASURES AGAINST DISEASES OF THE RESPIRATORY TRACT.*

BY D. H. BERGEY, M.D.,

OF PHILADELPHIA;

FIRST ASSISTANT, LABORATORY OF HYGIENE, UNIVERSITY OF PENNSYLVANIA.

It is not my purpose to speak of all the neglected prophylactic measures against diseases of the respiratory tract. I desire merely to emphasize several of the directions in which our efforts of prophylaxis fall lamentably short of our present-day knowledge of the subject.

The first of the points to which I wish to invite your attention is the detrimental influence of dust of whatever kind in causing irritation of the mucous membrane of the respiratory tract, thus paving the way for subsequent infection. It is an accepted fact that different kinds of dust operate in this manner, and yet there is no intelligent effort made to abate the evil wherever possible. In many industrial pursuits it is well known that the dust-laden atmosphere of the establishment is the primary cause of the prevalence of diseases of the respiratory tract, especially tuberculosis, among the operators. Modern improvements in machinery have done a great deal toward ameliorating the evil, but these alone are insufficient to overcome the detrimental influence of the dust.

In discussing a subject such as this I am well aware that I am going outside the domain of pure medicine into that of Social Hygiene, but I earnestly believe that the medical profession must first be aroused to a sense of the importance of the subject before it will be possible to reach the ears of the industrial world.

Our efforts at ameliorating the evils of this nature, besides insisting upon the introduction of machinery designed to limit the production and to assist in the abstraction of dust from the establishment, should be directed toward regulating the hours of employment in such establishments. Röpke (*Centralblatt f. allgem. Gesundheitspflege*, 1900, Sonder-abdruck), in a comparative study of the prevalence of diseases of the respiratory tract in the metal grinders of Solingen, Germany, and those of Sheffield, England, shows that in spite of the fact that the establishments at Sheffield are far less satisfactory and the arrangements for the removal of dust are poorer than at Solingen, the workmen at Sheffield present better health statistics. These results he attributes to the fact that at Sheffield the workmen are more generally abstainers, engage in athletic sports, live in better houses, and assume a better position at their work. The influence of prolonged sojourn in the open air, associated with athletic sports, is, no doubt, one of the principal factors in bringing about the better conditions of health among the Sheffield grinders. Lack of detailed study in this particular prevents us from making more than general statements upon this point.

Many other industrial pursuits are attended with the production of dust, and observation has shown that the prevalence of diseases of the respiratory tract is far more pronounced among those following such occupations than in those who engage in pursuits unattended by dust formation. Our knowledge of the great hygienic value of pure air as a prophylactic agent against disease suggests one of the most efficient modes of combating the detrimental influences of the dust in such occupations. If we can secure for workmen of this class a shorter working day, and at the same time encourage them in devoting the greater part of their leisure to outdoor exercise, we place them in a better position to overcome the injurious effects of the dust inhaled during their working hours.

Another form of dust which has become a menace to our lives in recent years is that generated in the streets in the larger cities. Since the advent of electric cars and smooth pavements the lives

*Presented to the American Climatological Association, May 14, 1903.

of the inhabitants of cities have been made miserable by the volumes of dust which are constantly formed on the streets. There is no doubt that this modern condition of city streets influences the apparently greater prevalence of diseases of the respiratory tract in recent years. It not only favors the more general dissemination of the specific micro-organisms but it also serves to lower the vitality of the mucous membranes of the respiratory tract and thus facilitates the invasion of these tissues by the bacteria when inhaled subsequently.

The remedies that may be suggested to abate this evil are not very satisfactory, though they may be made effectual to a certain degree. The efforts of the street cleaning departments are evidently too spasmodic to accomplish all that could be accomplished. More efficient cleaning of the streets at a time when they are practically unoccupied—the early morning hours—and the systematic flushing of the pavements will assist in minimizing the evil. Let us hope that in addition to a more efficient street cleaning we may, in the not far distant future, see all lines of transportation placed underneath or above the streets and the employment of draught horses superseded by other, non-dust-producing modes of propulsion.

The second point to which I wish to direct your attention is the great deficiency in the ventilation of so many of our public schools. It is a well-known fact that the constant breathing of air markedly vitiated by the excretions from the lungs of other persons exerts a detrimental influence upon the vital powers of the system. Nevertheless we find many of our public school buildings overcrowded and in consequence the way is opened for the more general distribution of the micro-organisms of disease when brought into such an overcrowded space.

The greater prevalence of such diseases as diphtheria, measles, and scarlatina during the autumn months can be definitely traced to the very intimate association of children in overcrowded and poorly ventilated school-rooms, and to the diminished resistance of their bodies to infection in consequence of the injurious effects of such overcrowding.

We have a general knowledge of the overcrowded condition of the public schools in different places, but, so far as I know, no systematic effort has been made to gather detailed information regarding the ventilation of the public schools except that just published by the State Board of Health of Ohio (1901) for all the schools in cities and towns of that State. This report is most interesting and important, and should be duplicated elsewhere. The tables given in this report show the number of square feet of floor space and the air space for each pupil in a room, as well as the ratio of window area to floor space. The investigation shows that 18 per cent. of the schools contain one or more rooms that fall below the minimum standard of 15 square feet of floor space, and a still greater number (28 per cent.) fall below the minimum standard of 200 cubic feet of air space, while 75 per cent. of the school buildings have rooms that are deficient in light in that they fall below the standard of a window area of 20 per cent. of that of the floor space.

Conditions such as these are, no doubt, very general throughout the country, since there is no probability that the conditions are worse in Ohio than elsewhere. With conditions such as these prevailing in our public schools it is no wonder that diseases of the respiratory tract are so readily disseminated amongst school children. Moreover, deficient ventilation and lighting are potent agencies in undermining the vitality of the bodies of growing children. It is of the greatest importance that the children of our public schools be protected from all detrimental agencies possible.

Among the prophylactic measures against diseases of the respiratory tract the two measures which appear to require our most urgent attention are the prevention of the formation of dust and the regulation of deficiency in ventilation and lighting of our public schools. The neglect of enforcement of sanitary laws in these two particulars is, no doubt, the cause for untold suffering. The regulation of sanitary questions of the magnitude of the ones under discussion must necessarily fall upon the State. The educated physician can do much, however, in creating public sentiment and directing it into proper channels of action.

## PUERPERAL INSANITY.*

BY J. WILL PALMER, A.B., M.D.,
OF AILEY, GA.;
SURGEON, S. A. L. R.R.

Puerperal insanity is a generic term used to include all cases of mental derangement incident to pregnancy and its sequelæ. When we remember the marked perturbation of the nervous system, even in some cases of pubescence, adolescence or climacteric periods, much less normal pregnancy, from reflex causes, from disorders of digestion and from the depravation of the blood, it is not strange that the same conditions which give rise to moral perverseness, to the loss of memory, to hysteria, or hypochondriasis should likewise prepare the way for the outbreak of the more pronounced forms of mental derangement.

I shall not dwell on the symptoms and differential diagnosis of mania and melancholia, per se, but shall speak of the relations of insanity mostly incident to pregnancy and its sequelæ, because it is too tiresome to treat of them here when we can find an exhaustive description of them in any standard work on insanity.

Puerperal insanity is conveniently subdivided into three classes: (1) Insanity of pregnancy, which is usually melancholia; (2) puerperal insanity proper, which comes on in a limited period after delivery and is usually in the form of mania, and (3) insanity of lactation, which is mostly melancholia.

* Read before the Medical Ass'n of Georgia, at Columbus, Ga.

The form of puerperal insanity may be mania, or melancholia, and sometimes these forms pass into dementia. Mania is almost always the form of insanity that occurs in puerperal insanity proper; melancholia is the form generally met with in the first and third classes, and if dementia occurs it is usually in these classes. Mania occurs more frequently than the others. The percentage of the different classes are: Insanity of pregnancy, 20 per cent.; puerperal insanity proper, 50 per cent. and insanity of lactation, 30 per cent.

Extensive collected statistics from various institutions devoted to the treatment of insanity claim that 7.1 per cent. of all cases of insanity of females are of puerperal origin, and that the disease develops during the child-bearing process.

As to the frequency of puerperal insanity in relation to the number of cases confined writers and present statistics vary considerably. My experience in the lying-in hospitals and insane asylums while in Baltimore and since I have been practising medicine, prove that we seldom meet with a case of puerperal insanity, although I met with two cases in 1902 and one in 1903. Summing up the tabulated cases of the best authors and writers and from latest statistics, it is sufficient to say that one woman out of every four hundred who is confined becomes insane. Dr. Williams, at Johns Hopkins, claims that the proportion is one out of 650.

There is a form of insanity not considered in the other classes known as transient mania during delivery. This is a peculiar form of mental derangement sometimes observed during labor and called temporary insanity. It is more accurately described as a kind of acute delirium, produced in the latter stages of labor by the intensity of the suffering caused by pains. It is most apt to occur as the head is passing through the os uteri, or at a later period, during the expulsion of the child. It may consist of merely a loss of control over the mind, during which the patient, unless carefully watched, might in her agony seriously injure herself or her child. Sometimes it produces acute hallucinations, as in the case described by Tarnier, in which the patient fancied she saw a specter standing at the foot of the bed, which she made violent efforts to drive away. This kind of mania, if it may be so called, is merely transitory in its character and disappears as soon as the labor is over. From a medicolegal point of view it may be of importance, as it has been held by some that in certain cases of infanticide the mother has destroyed the child when in this state of transient frenzy and when she was irresponsible for her acts. In the treatment of this variety of delirium one must of course try to lessen the intensity of the suffering, and it is in such cases that chloroform should be administered. After this temporary insanity passes off, we should keep the patient quiet for some time.

*Class* 1.—Insanity of pregnancy is without doubt the least of all three forms. The intense mental depression, which in many women accompanies pregnancy, and causes the patient to take a despondent view of her condition, and to look forward to the result of her labor with the most gloomy apprehension, seems often to be only a lesser degree of the actual mental derangement which is occasionally met. In many the attack of insanity can be traced as developing itself out of the ordinary hypochondriasis of pregnancy. A larger proportion of cases occurs in primiparæ than in multiparæ, a fact no doubt that depends on the greater dread and apprehension experienced by women who are pregnant for the first time, especially if not young. The period of pregnancy at which mental derangement shows itself varies. Most generally it is at the end of the third or the beginning of the fourth month.

We should not confound aggravated hypochondriasis with insanity of pregnancy as the former usually lessens after the third month, while the latter only begins after that date. Melancholia in insanity of pregnancy does not differ much from ordinary melancholia, although the suicidal tendency is often strongly and very generally developed, and moral perversions are not uncommonly observed.

Sometimes there is a tendency to dipsomania in the early months, which may be an exaggeration of the depraved appetite or morbid cravings, so commonly observed in pregnant women, just as melancholia may be a further development of lowness of spirit. Sometimes kleptomania is very characteristic of the disease.

*Prognosis.*—The prognosis may be said to be, on the whole, favorable, although there is little hope of a cure until after the termination of pregnancy.

*Causes.*—By far the most prolific cause of insanity of pregnancy is an hereditary predisposition to insanity that exists, and the event of pregnancy acting simply as the spark that fires the mine. The morbid dread of pregnancy aids in its causation. Besides hereditary predispositions there are other neuroses that have important influence in the causation, such as family history of epilepsy, drunkenness or hysteria. Anemia, which comes on gradually, has an effect in producing it.

The most recent theories show and claim that toxemia of pregnancy or a manifestation of autointoxication play an important part and claim that the toxemia is caused by toxins produced in the bodies of mother and child, and retained because of a lack of excretion or by incomplete metabolism or by both. These toxins may be the result of chemical decomposition of food and the waste material of tissue change largely increased by pregnancy. The insanity may be caused by an as yet unknown group of toxins which may exist in the body during the period of gestation.

*Puerperal Insanity Proper.*—True puerperal insanity has always attracted much attention from obstetricians, often to the exclusion of other forms of mental disturbance connected with the puerperal state. Puerperal insanity proper is the most interesting part of the subject. We may define it to be that form of insanity which comes

on within a limited period after delivery, and which is intimately connected with that period, because the mental disturbance which is usually acute confusional insanity is due to toxemic infection. Mania is generally the form of insanity met with, but by no means is it the only kind of insanity observed, for there are a considerable number, being well-marked examples of melancholia. There are also some peculiarities as to the period at which these varieties of insanity show themselves, which, taken into consideration and in connection with certain facts in their etiology, justify us in drawing a closer line of demarkation between them. My experience and the authority of the best writers lead me to say that all cases of acute mania come on within eight days after delivery and that all cases of melancholia develop after that period.

*Etiology.*—It is pretty generally admitted by all alienist physicians that hereditary tendencies form one of the strongest predisposing causes of mental disturbance in the puerperal state. In a large proportion of cases circumstances producing debility and exhaustion or mental depression have preceded the attack. Preceded by post-partum hemorrhage, severe and complicated labor, or they may have been weakened by over-frequent pregnancies, or by lactation during the early months of pregnancy. Morbid dread during pregnancy is sufficient to produce insanity before delivery, may develop into puerperal insanity after labor.

Shame and fear of exposure in unmarried women not infrequently lead to the disease. The anemia produced by post-partum hemorrhage is a potent factor in producing puerperal insanity. Mental impressions may be the determining cause in predisposed persons. The age of the patient has some influence and there seems to be a greater liability, at advanced ages especially, when such women are pregnant for the first time. The symptoms are intensified by disturbances of the abdominal or pelvic organs. The most recent theories and investigations attribute the causation of the disease to some morbid condition of the blood. The possibility and probability of an acute form of puerperal insanity, coming on shortly after delivery, being dependent on some form of septicemia is one that deserves most careful consideration and investigation on this subject.

There are several theories advanced as to the dependence of the disease being due to a morbid condition of the blood. The theory of uremic blood-poisoning causing puerperal insanity was originated by Sir James Simpson and supported by Dr. Donkin, who, after finding albumin in the urine of several patients, claimed that it might properly indicate the presence in the blood of certain urinary constituents which might have determined the attack, much in the same way as in eclampsia; that the acute dangerous class of cases are examples of uremic blood-poisoning of which the mania, rapid pulse, and other constitutional symptoms are merely the phenomena, and that the affection therefore, should be termed uremic, or renal puerperal mania in contradistinction to the other forms of the disease. They also claim that the immediate poisoning may be carbonate of ammonia, resulting from the decomposition of urea retained in the blood. The theory that hepatic insufficiency causes puerperal insanity originated and is supported by Budin, Penard and Dorland. Dorland claims that puerperal insanity is due to hepatic insufficiency and that the kidneys are only secondarily affected and that the morbid condition of toxic properties of the blood is not a disease of the kidneys or insufficiency of their functions. The tendency to-day is to ascribe the morbid condition of the blood and albuminuria to one and the same cause, namely, the presence in the blood of a certain toxin of unknown origin and constitution. The frequency of marked hepatic lesions in autopsies on puerperal women points to the probability of the toxin being liberated in the liver. Puerperal infection or toxemic infection is the direct cause of puerperal insanity, based on the fact that puerperal insanity occurs in the great majority of cases within the first ten days after delivery, the same period during which puerperal infection usually occurs. It is generally accompanied by elevation of temperature and other evidences of febrile disease. The clinical form in which puerperal insanity manifests itself is in most of cases that of acute delirious or confusional mania, closely resembling febrile delirium. The death-rate is much higher than in simple mania, death occurring from exhaustion usually with high temperature and rapid pulse. Post-mortem examinations, although apparently infrequent in either case, have shown grave involvement of the pelvic organs. Examinations of the pelvic organs during life show lacerations of the perineum and cervix uteri, which are the channels of infection in the puerperal woman. Puerperal insanity was a common complication of the puerperium in former times, but since the introduction of aseptic methods in midwifery there is a reduction of one-half of its incidence. Sometimes there are secondary conditions found, such as intrapelvic inflammations and consequent abnormal locations, fixations and congestion of the uterus, tubes and ovaries. It should be borne in mind that in each individual case many factors are indissolubly associated, the patient's mental breakdown being the result of several complex conditions, each reacting upon and intensifying the other. I think that the renal and hepatic theories are fallacies, although they may have some weight in producing the disease, because effects of faulty elimination of secretion altered in quantity and quality play an important rôle in the production of the unstable nervous condition of pregnant women. So we find the liver unable to perform the work thrust upon it and failure of skin and kidneys, with or without albuminuria, all of which certainly can and do induce faulty nutrition of the brain. There are many facts, as statistics of recent years show, to support the

belief that I have advocated that sepsis is by far the most important cause of puerperal forms of insanity. But it is strange that no one has yet ventured to assert that all puerperal cases are due to intoxication from either bacteria, or toxemic organ compound. In short, I venture to say that the *hereditary taint and morbid predisposition are the true causes of the disease, the puerperal condition being its immediate and exciting cause.*

Recent advances in bacteriology warrant the opinion that some day proof will be abundant of the universal belief that either toxemic or septic infection is a primary factor in all cases of psychosis of childbirth.

In no class of cases are gynecological investigations of more importance than in the study of the causation of puerperal insanity.

*Diagnosis.*—The diagnosis of puerperal insanity, cannot be made out from the symptoms. It is not a special variety of insanity symptomatically, but etiologically.

*Prognosis.*—The prognosis is favorable; 75 to 80 per cent. recover, but a large proportion die of exhaustion. In no class of cases of insanity is the prognosis so favorable as those of puerperal origin. The number of previous pregnancies seems to have little influence, but the age seems of more importance. The younger the patient, the better apparently is the prognosis. The disease may resolve itself into a consideration of immediate risk to life and of the chances of ultimate restoration of the mental faculties. It is an old aphorism, "That mania is more dangerous to life and melancholia to reason." Extreme rapidity of the pulse is indicative of a fatal tendency. If pulse be 120, conditions are grave, but as long as the pulse remains below 100 there is no immediate danger. Should there be development of phlegmasia dolens, the prognosis is rendered exceedingly grave. The most dangerous class of cases are those attended with some inflammatory complication with marked elevation of the temperature.

*Duration.*—The duration of the disease varies considerably; patients usually getting well in three months; but melancholia generally lasts longer than mania. When the patient gets well, it often happens that her recollection of the events occurring during her illness is lost; at other times the delusions from which she suffered remain.

*Lactational Insanity.*—This is a mental disturbance occurring during the period of lactation, usually coming on from six weeks to ten months after labor. This form of insanity is generally melancholia, and occasionally you meet with confusional insanity, which is much more transient than true puerperal insanity. There seems, however, to be more risk of the insanity becoming permanent than in other forms. Sometimes the melancholia degenerates into dementia and the patient becomes hopelessly insane.

*Etiology.*—Heredity taint is an important factor in producing this form of insanity as in the other forms. Prolonged or excessive lactation is considered the chief cause in producing lactational insanity. Careful inquiry, however, shows that certain conditions favoring toxemic infection are often present, as a mammitis, or mammary abscess sometimes precedes the mental disturbance. Defective uterine involution is considered as a factor. Lacerated cervix and endometritis have been found present in some cases. Its dependence on causes producing anemia and exhaustion plays an important part. Retained placenta, I believe, has force in producing it, as in a case of lactational insanity which I treated I found patient with discharge and retained placenta six weeks after labor. The toxemic effects from the retained placenta in this case giving rise to slight febrile condition proves that toxemic conditions are important factors in causing lactational insanity.

*Diagnosis.*—The occurrence of confusional insanity during the nursing period is the only diagnostic feature. There is nothing distinctive in the symptomatology. Three to four per cent. of all cases of insanity in women occurs during the nursing period.

*Prognosis.*—The prognosis is moderately favorable, from 40 to 50 per cent. recover. The danger to life is not great if the cause producing debility be recognized and at once removed.

*Mania and Melancholia.*—The symptoms of these forms of insanity are practically the same as in the non-pregnant state, consequently I will dwell only on the symptoms peculiar and incident to puerperal insanity, for you can find very extensive descriptions of the symptoms in almost any standard work on insanity. Mania is more frequent than melancholia, and occurs generally in puerperal insanity proper. This disease usually comes on in the first week of the lying-in period. It is almost in all, if not in all cases related to certain well-known symptoms of puerperal sepsis, fever nearly always being present. There may be prodromal symptoms, although they usually are not well marked. These consist in either depression, irritability or emotional instability. The outbreak usually begins with excitement, rapidly ending in incoherence. The usual feelings are proverbial. The patient may have attacks of violence, during which attempts are made on the life of the husband, the newly-born babe, or other children, if any.

These symptoms often have a religious basis; at other times they are based on delusions of jealousy. Usually the hallucinations and delusions of the patient are of a sexual nature and character. The most refined women will surpass the imagination of the most degraded in their obscenity and vulgarity of language and actions. The eyes are bright and face pallid, pulse quick, tongue dry and furred, bowels mostly constipated, urine high colored and scanty and appetite uncertain and abnormal, attempting to eat bedclothes, etc.; they also try to inflict bodily injuries on themselves, gouging at their eyes, etc. They seem dissatisfied with their physicians and nurses. They will often yield to suggestions and treatment of the physician on his first visit but

no longer, and then beg for new physicians. I experienced this in treating one case in which the patient became dissatisfied and refused to follow any of my suggestions or take a dose of my medicine. Another physician was called in, after his first visit he was treated likewise and the third physician was called, and after his first visit he received like treatment. Motor excitement is common. Some desire to remove their clothing and expose their persons while in others it is perhaps due to hallucinations of common sensation, rendering the weight or pressure of the clothing unbearable. The patient gets apathetic; there may be alternations of excitement and depression with incoherence as a dominant symptom, lasting for years. It may end in secondary dementia.

*Melancholia.*—This disease is most commonly in uterogestation and lactational insanity, and is often preceded by cephalalgia, tinnitus aurium, and flashes of light before the eyes, and other indications of debility when it comes on during lactation. But when during uterogestation, the accompanying delusions are generally exaggerations of the anxieties and whims of pregnancy. The advent of melancholia is more gradual. It may commence with depression of spirit without any adequate cause, associated with insomnia, disturbed digestion, headache and other indications of bodily derangement. Such symptoms, showing themselves in women who have been nursing for some length of time, or in whom any other evident cause of exhaustion exists, should never pass unnoticed. Soon the signs of mental depression increase and positive delusions show themselves. These may vary much in their amount, but they are all more or less of the same type, and very often of a religious character. I had one case in which insanity began and ended with religious delusions and hallucinations. The amount of constitutional disturbance varies much. In some cases, which resemble in character those of mania, there is considerable excitement, rapid pulse, furred tongue and much restlessness. Acute cases of melancholia coming on during puerperal state most often assume this form. In others there are less of these general symptoms; the patient sits for hours without speaking or moving; but there is not much excitement and this is the form most characteristic of insanity of lactation. There is always a strong tendency to suicide; which should never be forgotten in melancholia cases, as this may develop in an instant, and that a moment's carelessness on the part of the attendant may lead to disastrous results.

*Treatment.*—I will give the treatment of mania and melancholia mostly relative to puerperal origin, as we can find a descriptive treatment in nearly every work on insanity for general mania and melancholia. The indications for treatment are to check profuse, exhausting discharge; to support the patient's strength and to insure perfect quiet. With the first signs of trouble the child should be taken from its mother's breast and sight; liquid food should be given at frequent intervals, care should be taken to keep the rectum and bladder empty, the room should be darkened and its temperature should be regulated. We must calm the excitement and give rest to the brain. In acute mania there are three important things to do: The patient must have a sufficient quantity of suitable food and sleep; we must seek and remove the cause, bearing in mind that puerperal insanity is an infectious psychosis, the local source of infection should be sought out and removed, if possible. In some cases there is simple sapremia due to absorption of septic material from the birth canal. In others there is septicemia. In short, the treatment is about the same as in any case of puerperal infection. The streptococcic serum and intravenous infusion of formalin are used and have proved to be of no benefit, so far. In cases of purulent endometritis or retained placenta, curetting of the interior of the uterus and repeated irrigations will be required. Persons not needed in the sick-room should be excluded.

If the patient is poor and strength will warrant it, she will be best cared for in an asylum. Whenever possible, patient should be treated at home with trained nurses and much of our success in treatment depends on the nurses and especially their experience with the insane. We should have day and night nurses. The fact of having been in an asylum fixes a certain stigma upon patients, so let even this make us conservative in our orders. Every endeavor should be made to induce the patient to take plenty of nourishment to remedy the defects of the excessive waste of tissue and support her strength until the disease abates. If there is no febrile condition, give solid food as long as is possible, but if any febrile condition is present give only liquid food, as it will be better. Give the liquid food frequently and in small quantities. If patient refuses to take food, give it to them forcibly. Alcoholic stimulants should be given to the fullest extent, when well borne. In the early stages, or in mania, or in the excitant stages of melancholia the patient is better off without these stimulants, but under other circumstances they are to be given. At the onset a good purgation is beneficial, after that purgatives are harmful, but the liver and bowels should be kept in good condition by giving mild laxatives, such as a few grains of calomel, cascara sagrada, or sodium phosphate. When a diuretic is indicated give potassium acetate and infusion digitalis. If the skin is harsh and dry daily sponging with alcohol and warm water is very beneficial and it will aid to calm the excitement of patient. The heart should be watched and its strength maintained by small and repeated doses of digitalis, so as to keep the brain well nourished. Opiates should not be given unless in severe pain, as in cellulitis, as they have adverse action on the secretions. To produce sleep and calm the patient, which necessarily forms one of the most important points in treatment, of all remedies chloral hydrate stands first, and given

with potassium bromide its hypnotic action is increased. Trional is a very reliable drug for maniacal excitement and insomnia when given in doses of 30 grs. every two to four hours, to produce sleep and quiet the patient, but heart and bowels must be watched. I have found nothing to control the excitement better than hyoscine hydrobromate, given hypodermically in dose from $^1/_{150}$ to $^1/_{60}$, repeated once or twice daily, watching its effects. When the patient reaches convalescence she should have a good tonic, change of air and scenery and be taken to a healthy and quiet location. Great care should be exercised in allowing the visits of relatives and friends. There should be secured for the patient, rest, sleep, nutritious food, daily evacuation of the bowels, and little by little she should be brought back once more to old habits and the responsibilities of existence.

## THE ADAPTABILITY OF WESTERN TEXAS CLIMATE FOR THE TREATMENT OF CONSUMPTIVES.

BY C. H. WILKINSON, M.D.,
OF GALVESTON, TEXAS.

Desirous of adding my quota of experience to a cause which I consider more worthy of consideration than any other before the medical profession of our country to-day, namely, the proper caring for our American consumptives, and believing that my many years of observation upon the subject have borne some practical results, so far as benefiting these cases is concerned, I submit this article, trusting that it may fall before the eyes of some who may be thereby guided to a climate which certainly will be beneficial to all who resort to it in the early stage of phthisis.

It might be well to premise my remarks by the broad assertion that there is to-day, probably, no known specific for consumption. A victim once enlisted in the army of the Great White Plague has a battle to fight which almost invariably ends in his defeat, if he trusts alone for his cure to medicine. No reliance, therefore, can be placed in "vaunted cures," nor in any of the horde of "boasted methods" that flaunt from the columns of our American papers every day.

Not that medicine, however, is useless in consumption; on the contrary, at certain times and under certain conditions it is useful as an auxiliary to more natural and important methods of dealing with this disorder, and he who attempts to steer his cases through consumption, without the occasional aid of medicine, commits an error.

Turning away then in search of relief, from our Pharmacopeia, and from an exclusive medical system of treatment for such cases the important question which confronts us at the outset of our efforts is, What are we to do with these cases? Fortunately, nature has placed within our reach, and right at our doors, and practically accessible to all, a drugless remedy which answers the question and which can be relied upon, if taken in time, for the cure of human tuberculosis. That drugless remedy is climate.

*Western Texas.*—Without consuming space upon the climates of New Mexico, Arizona and Colorado, the three most famous territories in America, and justly so, for the relief of consumptives, or upon other less favored localities, the writer simply desires to introduce his adopted State to the consideration of the medical profession of this country, with the sole object in view of pressing her claim for recognition as one of the most favored spots on earth, for the sure and prompt eradication of phthisis pulmonalis, if such cases take advantage of her climate in the early stage of that disease. Western Texas, that portion of the great Lone Star State especially adapted for the cure of phthisis, and of which this article is particularly descriptive, comprises all that territory situated between the Colorado River on the east, and the Rio Grande on the west; the thirty-second parallel of north latitude on the north, and the Gulf of Mexico on the south. In extent it is larger than all New England, and is easily capable of accommodating over 10,000,000 human inhabitants.

The surface of this country is mainly undulating, except along its southern boundary, which is level, and rises from an elevation of 500 feet in the east to one of 5,000 feet or higher, along its western border. Within the limits of the country just described, it is safe to say, can be found the natural sanitarium of the world. The winters here are comparatively short and mild, while the summer heat rarely if ever attains a degree to be oppressive, and summer nights are always cool and delightful.

Three or four important lines of railroads traverse Western Texas, so that most portions of the country can easily be reached by health seekers, and along these lines the luxuries of life can nearly always be found, if proper effort is made to procure them. Moreover an abundance of pure water can readily be obtained, as likewise an abundance of nutritious foods.

Cities, towns and villages, to the number of a hundred or more, are interspersed all through this region, and the residents thereof are, in the main, quiet, peaceable and intelligent. A few years ago nearly all of Western Texas was one vast cattle ranch, or, more correctly speaking, a continuous line of them; but to-day most of these pastures have been converted into beautiful farms, while the cowboy and the Indian have retreated before the school teacher and the industrious farmer.

*The Climate.*—As stated above, the winters and summers of Western Texas are comparatively mild, the degrees of heat and cold never attaining the extremes observed in many other localities resorted to by health seekers, consequently invalids are enabled to be in the open air for a longer period of time than perhaps in any other State in the Union. A remarkable peculiarity of the atmosphere in Western Texas is shown by the fact that, in the center of this

health district in midsummer, fresh meat suspended in the open air will remain there indefinitely without tainting; and incised wounds under any sort of care, rarely ever suppurate. In other words the atmosphere here is inimicable to pyogenic germs, and in this property its antibacillary qualities no doubt reside. It has been asserted by authorities on phthisis that there is nothing specific in any atmosphere for the disease, but in the light of recently discovered facts this statement to the writer seems questionable. The climate of Western Texas will restore to health 85 to 90 per cent. of all phthisical cases consigned to its care in their incipiency; and this, too, with so much certainty that climate in this instance could properly be styled specific.

Nor are its benefits confined to incipient cases alone, since hundreds of human beings to-day are enjoying excellent health in Western Texas, who were carried there upon their beds in search of health many years ago.

*The Best Places in Western Texas for Consumptives.*—So large is the territory under consideration that a description of the various resorts to be found there would be out of the question in an article like this, therefore only brief mention can be made of some of them, except of one.

San Angelo, at the western terminus of the G. C. & S. F. R. R. and Llano on the Austin Branch of the Central Pacific, are excellent and famous health resorts, situated respectively about 1,800 and 1,000 feet above tide water and each quite accessible by rail.

Marfa and Fort Davis are further west, and very much higher, being 5,000 feet above the sea. These are along the line of the Southern Pacific Railroad, but are not so easily reached as the first two mentioned by reason of their distance. Perhaps the best locality for consumptives in all Texas, if not the best adapted place in the world for such cases, is at Comfort. This little German village of 600 inhabitants is situated in Kendall County, on the San Antonio & Aransas Pass Railroad, just 52 miles northwest of San Antonio. It is about 1,700 feet above sea level, and is surrounded by hills and mountains of considerable magnitude. Along the south side of the village runs the Guadaloupe, a most beautiful stream of clear water, while the whole face of creation around is dotted with elegantly kept farms teeming with luxuriant verdure nearly all the year round.

The air here is pure, elevated, crisp and dry, and for the most of the year it is warm, thereby constituting an ideal lung food. This atmosphere is inimicable to putrefaction, and the bacilli of tuberculosis rapidly die out under its strong influence. Here one never feels fatigue, and therefore "that tired feeling" so often complained of by denizens of lower districts is never heard of.

Comfort, being only fifty-two miles from San Antonio, and on a railroad, is quite easily reached from that city. There are some excellent physicians located here, and nearly any luxury desired can be obtained without delay. It is at Comfort, Texas, where Camp Reliance is located, and where invalids, both male and female, reside in tents all the year round for the cure of their disease, relying on the "open air" method.

*How to Reach Comfort, Etc.*—Probably the first question suggested to the reader of this article would be: First, How can one reach Comfort? Second, What would the round trip cost? Third, How long should one remain in that climate before he could safely consider himself cured? Fourth, What accommodations are obtainable out there? And, fifth, What vicissitudes would one have to undergo while remaining out in Texas?

These are all pertinent and practical questions, and experience shows that they are the usual inquiries made by prospective health seekers from Texas physicians. The writer can only answer the first and second inquiry by taking San Antonio as the point of departure for the invalid.

First, as is well known, this last-named city is the great Mecca of the southwest for consumptives. Here they annually flock by the hundreds, and from San Antonio many of them scatter out in all directions in search of better places, as information directs them. There are four great lines of railway running into San Antonio, and all of them transport invalids to this section. These lines are the Southern Pacific, the San Antonio & Aransas Pass, the Missouri, Kansas & Texas, and the Great Northern railroads. Take whichever route is most conveniently reached; though the S. A. & A. P. R. R. has established a route out of Chicago via the M., K. & T. R. R., by which passengers can go through to San Antonio without change of train, a great advantage to the invalid traveler. From San Antonio your trip of fifty-two miles is over the S. & A. P. R. R., familiarly called the S. A. P., a beautiful and picturesque route, and the fare is $1.55 each way.

Second, At Comfort or anywhere around in the neighborhood good accommodations can be obtained in hotel, on ranches or in tents, at from $25 to $30 a month, and your stay in this country should be from four to six months, according to the severity of your case, in order to secure permanent benefits therefrom. Thus, in mild cases, the round trip from San Antonio to Comfort and back should cost you not exceeding $200 for a six months' trip, including everything. As a matter of course, severer cases require longer stay, while those bedridden who go should expect to remain there a year, or even longer. In answer to Question 5 the writer will state that there are no vicissitudes in store for invalids who go to Comfort, over and above occasional inconveniences common to all travelers. The climate there is nearly perfect; the people (nearly all German) are quiet, honest and industrious, and sociable, and it is this very character of the people and quality of the atmosphere that make Comfort the ideal place for invalids to go to.

There is also an abundance of nutritious food to be found in that country, such as milk, eggs,

butter, fresh meats and vegetables,, while game and fish abound plentifully nearby.

Finally, the invalid is within "hailing distance" of civilization, a most important point to be considered in treating these cases, telephone and short railway connections being had with San Antonio, the largest city in the southwest and the most attractive one in the State.

The proximity to so well a supplied base as San Antonio, with its luxuries and attractions, along with all the natural advantages just enumerated, make the little village of Comfort, in the opinion of the writer, far ahead of any place in Texas, if in fact it is not the superior of any to be found in all this country, as a resort for the proper accommodation and treatment of consumptive cases.

Since writing the above, it is learned that a station has been established at Camp Reliance, on the S. & A. P. R. R., just 50 miles from San Antonio, and that tourists are finding this an excellent resort to stop at. The writer would be pleased to give further information to anyone who might desire such upon the climate and resorts of Western Texas.

---

## PERINEAL PROSTATECTOMY WITHOUT OPENING URETHRA OR BLADDER—UNSATISFACTORY RESULT—SUBSEQUENT PERINEAL CAUTERIZATION OF EN COLLARETTE NARROWING OF BLADDER ORIFICE—RECOVERY.

BY JOSEPH RILUS EASTMAN, M.D.,
OF INDIANAPOLIS, IND.

The case of prostatic hypertrophy described briefly in the following report concerned an attorney sixty-nine years of age. He was below medium in stature, rotund and phlegmatic. His life in the nature of his calling had been sedentary, and for many years he had drank alcoholic beverages in moderation. He had not been a voluptuary. Constipation had never annoyed him in a notable degree, but an examination of the rectal mucosa disclosed general venous congestion and varicosities. There were no marked evidences of general sclerosis. There was no arcus senilis. The arteries were soft.

The symptoms recited at the writer's first examination and which had begun to appear four years previously, were the classical ones, dependent upon interference with the function of micturition. Undue frequency of micturition had increased until the man was disturbed 12 or 15 times during the night, mostly during the after part of the night. Micturition was hesitating, interrupted and followed by dribbling, the urine falling directly to the ground, not describing the normal parabolic curve.

The amount of residual urine varied between six and eight ounces. There had never been complete retention. Pyuria, slight hematuria, muscular spasm and characteristic pain were present. Bacteria, including *Bacilli coli* and *Staphylococci* were found in the centrifuged urine. Ammoniacal fermentation had begun. The odor of the urine was very pungent. There was present a trace of albumin. The urine also contained hyaline casts and much bladder epithelium. The reaction was alkaline, and the specific gravity hung about 1.024. There was slight intermittent polyuria.

The withdrawal of the urine through the catheter elicited the assurance that the bladder had not lost its expelling power. The posterior urethra was found to be lengthened, the distance from the anterior layer of the triangular ligament to the bladder orifice having measured 3½ inches.

Most small instruments entered the bladder, but not without difficulty, the handles being deflected slightly toward the right. The Coude and Bicoude catheters entered no more easily than the straight instruments or those with the Van Buren or Guyon curves. The cystoscope revealed nothing except that the "bas fond" bulged upward. With stiff instruments, complete entrance into the bladder was not effected without extreme depression of the handles. Upon examination per rectum, the prostate was found to be smooth, harder than normal, and enlarged to four or five times its normal size, the right lobe being slightly larger than the left.

As is often the case, the patient was not aware that he was seriously afflicted, had received no treatment, and at the suggestion of prostatectomy, demurred. Therefore he was put to bed, and continuously catheterized for two weeks, with no improvement.

In view of the inability to demonstrate an intravesical growth with the cystoscope, the general bulging upward of the "bas fond," and the smooth, general enlargement of the two lateral lobes, a perineal prostatectomy was performed. The prostate was exposed by an inverted Y incision, and the capsule was split transversely. The gland was removed, mostly by excochleation, but partly by morcellement. This was accomplished without opening the posterior urethra. The floor of the prostatic urethra was freed with serrated scissors.

The patient being a very poor subject, in a general way, for surgery, as shown by the way he bore the operation, and the urine being highly infectious, the writer had not the temerity at this time to permit the bladder contents to escape through the perineal wound, fearing uremia or sepsis or both. It was hoped that the obstruction was entirely removed, since by sweeping the convexity of the curve of a large sound across the mucosa of the bladder floor, and following it with the index finger in the perineal wound, it could readily be determined that the floor of the prostatic urethra and bladder were quite thin. It was subsequently proven, however, that the obstruction was not removed. The residual urine was decreased in amount, but at least three ounces remained. The other symptoms were in nowise improved. After three weeks the perineal wound,

which had not yet closed, was reentered and the posterior urethra opened.

Upon passing the finger through the posterior urethra, a thin stricture-like obstruction was met at the bladder orifice which raised the bladder outlet at least a half an inch above the level of the bladder floor. This stricture-like obstruction was cut down by galvanocautery division of the urethral floor. This was done with the instrument devised and used by Dr. Wishard, of Indianapolis, for cauterization of the prostatic collar through a perineal incision.

There is nothing in the history of this case after the second operation, which is worthy of note. A large perineal drain was inserted and left in place for ten days. After its removal, the perineal wound rapidly closed and the posterior urethra was dilated with full-sized sounds twice a week for a month. The urine is now (eight months after operation) quite clear and is voided every four or five hours during the day. The patient is gaining flesh and sleeps undisturbed all night.

The writer has designedly omitted to speak of the minor details of treatment pertaining to bladder irrigation, internal medication, and so forth, in this case, for the reason that no unusual agents of any kind were used. He wishes to submit that, had he this case to deal with again, no change would be made in the manner of operating. The man being an unfavorable subject for surgery, and the urine being laden with pus microbes, performance of the operation in two stages, was certainly not without its advantages. The perineal opening with its granulating wall, it may be assumed, safe-guarded in a measure against sepsis and uremia, as Senn claimed in presenting his two-stage suprapubic cystotomy.

In many cases, in the writer's belief, it is more surgical to cauterize the prostatic collar through an aseptic perineal incision under guidance of the eye than to imperfectly accomplish this blindly with the Bottini incisor, searing the bladder mucosa with hot smoke and steam for which there is no exit. The only valid argument in favor of the Bottini operation as opposed to the perineal cauterization is that in the latter there is slight danger of septic or uremic poisoning through the ungranulated defect. This objection is met by executing the operation in two stages.

The writer disclaims the carrying out of a premeditated plan of a two-stage operation in the case cited, but felicitates himself that, through lack of temerity in this particular case, he was perhaps led in the right direction. It is possible that others in the future may see fit, in certain debilitated "prostatikers" with considerable general enlargement and constricting obstruction of the bladder neck, to remove the two lateral lobes, and after permitting the perineal defect to granulate, to cauterize the constricting collar.

Should their success with this method be as gratifying as his own, the author will feel fully repaid for recording his experience.

## MASTOID DISEASE AND MENINGITIS.

BY SEYMOUR OPPENHEIMER, M.D.,
OF NEW YORK;
OTOLOGIST TO THE GOUVERNEUR HOSPITAL; LARYNGOLOGIST TO THE BELLEVUE-UNIVERSITY MEDICAL COLLEGE DISPENSARY; INSTRUCTOR IN LARYNGOLOGY AT THE BELLEVUE-UNIVERSITY MEDICAL COLLEGE; FELLOW OF THE AMERICAN RHINOLOGICAL, LARYNGOLOGICAL AND OTOLOGICAL SOCIETY; ETC.

THE increased attention and critical study of the cerebral complications of aural affections and the brilliant results obtained by the prompt recognition of the nature of the brain lesion or lesions, with the adoption of efficient and radical surgical measures, have led to the obvious conclusion that in many cases of meningitis the primary origin of the affection could be directly traced to some portion of the auditory apparatus. Friedreich has clearly emphasized this view in his statement that the importance of aural disease in the production of secondary diseases of the meninges cannot be overestimated and that the doctrine of otitic cerebral disease now forms one of the most important chapters of otology.

In practically all the cerebral complications of mastoid disease, with the possible exception of isolated, deep brain abscesses, the presence of inflammation of the meninges to a greater or lesser extent, accompanies the more prominent lesion of epidural abscess or sinus thrombosis and the symptoms of the former are masked by those of the latter, or the brain membranes are involved to such a slight extent that recognition is impossible. When the external pachymeningitis, as will be seen later, remains localized and is the result of infection with pus-producing organisms, the condition assumes that of an epidural or extradural abscess, and, as in this particular instance, the condition is primarily one of meningeal irritation, followed by the local pus collection, so may the pathological process possess an obverse aspect and the meningitis may be but the result, especially when extensive, of an infective phlebitis or pus collection extending beyond its boundaries and producing a condition that is rapidly fatal in a short time.

During the course of a mastoid empyema and most frequently in young children, a condition of meningismus or pseudomeningeal symptoms may develop and the difficulties surrounding the selection of proper treatment will be almost insuperable until a sufficient time has elapsed, in order that the value of the various symptoms may be correctly interpreted. Such a case came under my observation several years ago, in which, in consultation, a child of seven years was seen with a history of a purulent discharge from the right ear for one year following scarlet fever. Five days before coming under my observation she had been exposed to a draft and during that night she was awakened by intense, throbbing pain limited to the mastoid region of the same side. The aural discharge rapidly diminished in amount and within twenty-four hours had practically ceased and the mastoid showed beginning swelling of the soft tissues. The child at my first examination was worn out with the constant pain, the mastoid process was exquisitely tender to the

slightest touch and was red and swollen. There was a large perforation in the posterior inferior segment of the membrana tympani and the remains of inspissated pus in the canal and middle ear. The symptoms calling attention to apparent meningeal involvement were intense headache limited to the right side and especially referred to the temporal and occipital regions. The temperature was 103° F. and had been 100½° F. in the morning, while the entire symptom group indicated an intracranial extension of the infection. Immediate operation was advised, but was absolutely refused, so ice dressings were applied to the mastoid. The canal and middle ear were irrigated at frequent intervals with a warm normal salt solution and free drainage was established from the middle ear by removing the retained purulent material and enlarging the opening in the drum. Complete recovery promptly ensued and after a lapse of three years the child has had no further trouble with the ear. While this case recovered, such a result cannot be expected, as a rule, and while it is here cited to demonstrate the prompt subsidence of meningeal irritation in this particular instance, yet operation would have been equally successful and would have removed the dangers in the future to which she may be subjected, from the presence of the suppurating middle ear, which still remains.

The meningeal irritation may not necessarily advance as far as a true inflammation, but the symptoms may be caused by congestion and edema of the brain coverings, but this at first, and especially in the absence of operative treatment, is practically undistinguishable from an infective intracranial inflammation, except by a careful study as shown by the course of the disease. The meninges may be invaded either from the middle ear or by the involvement of the mastoid process, and it is with the latter especially that we have here to deal, although it is almost impossible in cases where the destruction of tissue is extensive to determine the exact path of infection with any degree of certainty.

The proportion of reported deaths from the intracranial complications of aural disease, and especially as regards the relation of the mastoid and meningitis, is suspiciously small, yet, we think, were due credit given to the aural origin of many fatal cases of meningitis associated with abscess and sinus phlebitis, the proportion would be materially augmented. Especially is this so in children, in whom the presence of a meningitis accompanying an acute or chronic auditory infection is not at all uncommon. Gruber found in 40,073 hospital deaths of all kinds, intracranial disease in 1,806, and of these 232 were caused by disease of the ear, while meningitis was present in 115 instances. A fact of considerable interest elicited in this connection being that of the latter number dying of meningitis, the male sex greatly preponderated, 87 being males, while but 28 were of the opposite sex. Korner in 151 observations found diffuse meningitis in 23 as the predominant pathological change, and in many of the other complications patches of adjacent meningitis were constantly present. This is shown by the condition of the meninges in brain abscess, as a large proportion of these pus collections, which can be safely estimated at at least one-third, are the direct result of otitic disease, the infection having been carried by means of the meningeal tissue. As further showing the presence of this factor, McBride in 44 cases of fatal ear disease, found 12 who died of meningitis and in three which were classed as brain abscess on account of the predominating symptoms of that affection, there also existed a condition of diffuse meningitis. The large statistics of Barker, embracing 72,000 cases of all kinds of disease, show 45 fatal cases due to ear disease. In a study which he made of 50 fatal cases 72 per cent. were due to the association of meningitis and pyemia. This author asserts that of the ordinary complications of ear disease, more than nine-tenths probably consist of meningitis, septic phlebitis and pyemia.

While the brain envelope may be involved in limited or extensive areas dependent upon the degree of the infection, the variety of the inflammation may be different in some cases and the ordinary pachymeningitis may be present either as the internal or external variety. Cerebrospinal meningitis may also exist at the same time as a mastoid empyema, but no relation usually can be traced between the two, and as the effects of cerebrospinal meningitis are produced secondarily upon the ear and are not the result of infection from the auditory apparatus, they will not here be considered.

As regards infection, practically but two forms of otitic meningitis may be considered, the first resulting from infection by absorption into the circulation and differing from many cases, inasmuch as the exact path by which the morbid material is carried from the ear to the meninges is unknown; while the other variety depends upon the extension of the inflammation by contiguity from the mastoid region to the dura and from there to the other membranes enveloping the brain. The former variety is rapid in its onset, usually diffused, and once established is necessarily fatal, while the latter form consists of a gradual process, usually localized in its incipiency and when diagnosed early is susceptible of cure by a radical operation. Poli relates a remarkable case of the former variety in which the rapid diffusion of the infection to the meninges and the entire cerebrospinal axis was most astonishing. Purulent leptomeningitis, therefore, is usually fulminating, sets in suddenly and terminates in but a few hours, or may continue before a fatal issue ensues for several days. While the localized focus analogous to an epidural abscess is more or less chronic, with mild symptoms which may apparently intermit from time to time before a regular course is established and which may last for several weeks or even months.

The internal form of pachymeningitis corresponding to the subdural or intradural abscess is comparatively rare, and is usually the result of a

circumscribed area of dural inflammation, becoming softened, corroded and perforating, with the deposition of exudation and infective material in the subdural space. Under these conditions should the pia and arachnoid become agglutinated to the dura, pus may accumulate in this situation and exist as a subdural abscess with softening and disintegration of the adjacent brain tissue. Should the membranes, however, not limit the spread of the infection, a general diffuse leptomeningitis will necessarily ensue.

In addition to the acute inflammatory changes of the meninges, a serous form has also been described, and, like the other, may originate from an otitis and compel surgical intervention. Müller has paid especial attention to this variety, and describes two cases occurring in his practice, in both of which a diagnosis of cerebral abscess was originally made, but no pus collection was found on operation. He considered the correct condition in one to be that of chronic serous external meningitis and an acute internal serous meningitis in the other. The symptoms in the first patient indicating a compressing, cerebral abscess and on account of the sensitiveness of the left mastoid process in connection with a preceding otitis, left little doubt of the otitic origin of the intracranial complications, as evidences of the compression within the skull were slow pulse and a congested retina, while motor weakness, headache, hyperesthesia of the right side, vomiting, vertigo, numbness and slight elevation of temperature, indicated an abscess of the temporal lobe, although there was no aphasia. The absence of stiffness of the nucha and high fever with a regular pulse, were against the presence of meningitis. The operation, however, showed the absence of pus, but the excessive amount of serous fluid found when the brain was exposed indicated a pathologic increase. The dura presented a degree of firmness quite unusual, and it was then considered that the affection was evidently a beginning suppurative meningitis in the stage of hyperemia and serous effusion. The chronic character of the process was shown by the long-continued headache preceding surgical intervention, while the disturbance in gait and equilibrium still persisted, showing that permanent lesions had been induced. In the second case the diagnosis remained in doubt for several weeks after the operation, but gradually the threatening symptoms induced by the compression ameliorated, the serous effusion diminished and the case recovered without further incident.

The location of the original focus of infection in the mastoid or its immediate vicinity will determine to a great extent the initial focus of meningeal infection. It may, however, affect the entire surface when a basilar meningitis is apparently the form of predilection, or the infection may remain localized with resultant discrete abscess, and as the course of the extradural abscess is very slow, adhesions form between the dura mater, pia mater and brain and act as a barrier to the development of a purulent leptomeningitis. While the abscess so formed may remain quiescent for a lengthy period, further infection from this focus may ensue and a purulent leptomeningitis will follow, such a case being reported by Barkan. Secondary inflammation of the meninges, however, varies in intensity and extent in different cases, depending upon the quantity and quality of the infective elements and the power of resistance of the individual tissues. In some a profuse plastic lymph may be thrown out and the inflammation will thereby be limited in extent, while in others no such means of protection are afforded and a diffuse purulent meningitis results, so extensive as to sometimes involve the cord for a considerable extent. Two locations, however, are commonly the seat of choice, the temporosphenoidal lobe and the cerebellum, the particular direction in which the infection takes place depending to a measure upon the anatomical peculiarities of the individual case.

The precise mode of the extension of the infection is subject to great variations, but in a general way it takes place either by direct continuity or indirectly by way of the blood or lymph channels. By direct infection from the mastoid, caries of its inner wall may lead to sinus phlebitis, which in turn may give rise to a septic meningitis. Though the path of infection may be sometimes obscure, it is usually more or less direct, as the area of meningitis is almost invariably on the same side as that of the mastoid empyema. Septic phlebitis of the venous radicles leading from the mastoid is also probably one of the commonest methods by which the septic material is conveyed to the meninges, this route being aided in a considerable degree by the free inosculation of the small vessels of the ear and dura. In this way the infection may be carried through apparently healthy bone.

The dura of the posterior fossa may especially become involved by direct carious processes of the mastoid, or by necrosis, erosion or atrophy, the last form being seen in cholesteatomata. The extension of mastoid disease to the membranes of this region depends to a great extent on the arrangement of the system of pneumatic cells, and as the cells are lined with epithelium they permit the suppurating process to go on rapidly, and if it extends as far as the inner table the infection spreads more rapidly to the meninges than if it were separated from the brain membrane by a compact layer of bone. The relation of the route of the infection to the arrangement and number of the pneumatic cells also varies in the child and the adult, and, as a result of the anatomical structure of the mastoid in early infancy, inasmuch as it possesses but few cells, while the posterior wall is strongly developed, it renders disease of this region in the infant less apt to invade the meninges of the posterior fossa than is the condition in adults. Another factor, which, however, is not of as much importance in regard to the mastoid region as in that of the tympanic cavity, is the presence of occasional clefts or fissures in the bone, the presence of such apertures

of necessity bringing the disease process of the mastoid in direct relation and close approximation to the dura.

When a purulent leptomeningitis develops the pathogenic substance is carried into the arachnoid in various ways, either by perforating the dura or by means of minute channels which leave no mascroscopical evidence. The original area of infection usually develops in the immediate vicinity of the diseased dura and travels from the base of the brain to the convexity of the same side and also across the base to the convexity of the other side, if the process be extensive. The pus is found in the furrows between the convolutions and also in disseminated patches, while the pia mater is hyperemic and edematous. The extreme difficulty of tracing the paths of infection from the ear to the meninges may be sometimes insurmountable. In this connection Wilson has reported a valuable case of leptomeningitis of otitic origin, in which the mastoid contained a deep-seated cavity filled with pus, but no granulations nor softened bone. The symptoms then improved for a day, but rapidly grew worse and the patient died comatose. The autopsy showed a large area of leptomeningitis over the base of the brain and the whole right lobe of the cerebellum, which also contained a small abscess. The dura over the upper surface of the temporal bone was healthy except at the junction of the petrous ridge with the squamous portion, where there was a foramen leading through the ridge from the posterior to the middle fossa and filled with pus.

The nature of the micro-organisms present in the mastoid empyema play some part in the virulency of the meningeal inflammation and a reduction of the virulency of the specific micro-organisms present in a given case effects the occurrence of a circumscribed meningitis, which, of course, is the preliminary condition of nearly all brain abscesses. If, on the other hand, the bacteria be of a virulent character and if they reach the inner surface of the dura, the inflammation rapidly spreads and a diffuse leptomeningitis is the result. For these reasons a brain abscess is rarely found with acute mastoid empyema and with the bacteria attenuated, an infection of the brain substance from the circumscribed meningitis rarely occurs and the patch of meningeal inflammation may exist independently for a long time. Various organisms may be found in the meningeal exudate, but the staphylococcus and streptococcus are by far the most important. Kirchner reporting a case of purulent meningitis with the staphylococcus as the only organism present, while in Hamilton's case of mastoiditis with the pia and arachnoid at the base congested and infiltrated with thick, yellow pus, both cultures of the blood and pus, gave pure colonies of the streptococcus pyogenes.

As illustrating the formation of an extradural abscess from a localized infective meningitis, which originated from a mastoid empyema, the following case well shows the sequence of events and the results obtained by early operation.

C. M., male, aged thirty-five years, has always been in good health until two years ago, when, following a severe attack of influenza, severe pain developed in the left ear and continued for several days, when it gradually diminished in intensity and finally disappeared. This occurred several times within the two years since the primary attack, but as it disappeared spontaneously nothing was done for it. One week before he came under my observation the pain had again commenced and instead of ameliorating was gradually increasing in intensity, so that he was forced by its violence to seek relief. No discharge had been noticed at any time and when the ear was examined the canal was perfectly dry, but exceedingly red and inflamed, especially along the posterior wall, while the tympanic membrane was violently inflamed and was pushed forwards, as if the tympanum contained fluid. The posterior and superior wall in part projected into the lumen of the canal, and all the parts were exquisitely tender. The auricle was pushed forwards and the mastoid was swollen and tender. The temperature was 100° F., while the bowels were constipated. Immediate operation was advised and accepted, and after the usual preparation of the patient the mastoid was opened and found filled with an offensive pus, while there was extensive destruction of bone tissue. But little pus was found in the region of the tip of the mastoid, the greater part of it being in the cells in immediate relation to the antrum. The pus and necrosed bone of the mastoid and antrum was thoroughly removed and free communication established through the tympanum and external canal by the above means. The tympanic cavity was found full of purulent material. Marked relief to the symptoms was obtained and he progressed through the usual course for two weeks, with the mastoid wound healing nicely, when he again complained of pain in the former situation and also located a painful area extending still further back than the mastoid tenderness. Within a few hours he became slightly delirious, food was vomited, his mental condition was sluggish, and he complained of severe pain in the occipital region. The temperature was 104° F. and the pulse 120. No other symptoms that would in any way aid in clearing up the condition could be ascertained. The original mastoid wound was then enlarged backwards and the brain cavity was opened, the dura immediately projecting outwards as a red, granulating, non-pulsating mass. Free incision was made into it, about three drams of pus evacuated and an abscess cavity was found walled in by masses of plastic lymph, although the meninges were beginning to become inflamed in all directions as far as could be seen. The pus was thoroughly washed out, the granulations removed and the usual dressings applied. The pain immediately ceased, and no further trouble was experienced, as the patient made an uneventful recovery. No route by way of which the infection traveled could be ascertained.

A somewhat similar case to this is recorded

by Buck, of a man of fifty-seven years, of strong constitution, who had during a period of ten years five distinct attacks of acute otitis, from all of which he apparently made a good recovery. The present attack had lasted for seven weeks, with headache and dulness of hearing, but no discharge. The posterior wall of the canal was swollen, the membrana tympani was injected and the mastoid was tender on pressure. The drum membrane was incised, but no pus escaped, and he experienced relief for about a week, when the pain returned and the mastoid became swollen. An incision was made through the mastoid periostium and some relief was obtained, further operation being refused by the patient. The following day he became unconscious, pupils were non-responsive, face flushed, head hot, pulse 120 and full, while the breathing became stertorous and death occurred the same night. The autopsy showed a purulent basilar meningitis and a free communication between the mastoid antrum and the cavity of the sigmoid sinus, the two forming an irregular cavity filled with pus.

When a mastoid empyema is about to infect the meninges there is almost invariably marked local pain, usually associated with fever. When such a condition occurs, especially in the presence of a diminishing aural discharge, the patient should be considered in serious danger of cerebral complications.

Headache is probably the earliest and most pronounced of the meningeal symptoms, and while at first it may be more or less localized to the temporal or occipital regions of the affected side, it later becomes generalized, even though the patch of meningitis remains localized, the headache may in some cases be intense and general throughout the whole course of the disease. Dizziness, auditory and visual hyperesthesia, mental weakness, delirium and convulsions are also seen, but are subject to considerable modification by other existing complications, such as abscess with high temperature and slow pulse, or sinus phlebitis of a septic form, accompanied with rapid diurnal changes in temperature. Usually the temperature is high and remains constant with but few fluctuations, but it may vary from 101 to 105° F. Photophobia, vomiting and local or generalized convulsions may also indicate meningeal involvement, while in children general convulsive symptoms are common owing to the high grade of fever usually present from the onset of the meningeal irritation.

The respiratory changes may come on quite early and while in ordinary meningitis breathing is rapid and irregular, with the pulse small and frequent, in the basilar type Cheyne-Stokes respiration is frequently noticed, especially when the posterior cranial fossa has been implicated. The younger the patient the earlier delirium appears, but it is not necessarily characteristic of this form of meningitis as it may not occur until toward the fatal termination of the case and is present in any of the forms of the intracranial complications, although if it should appear early, it may be of value in indicating a complicating meningitis, but only in connection with other symptoms. In other instances it will be absent during the entire course of the disease, the patient slowly passing into a condition of coma and death. The ocular phenomena in basilar meningitis, also present some points of import in this connection, although the optic disks are usually normal as it takes a week for the development of optic neuritis when the disease is limited to the posterior fossa, yet the third, fourth and sixth nerves are sometimes involved; the most important being, in this connection, the involvement of the third nerve, producing at first contraction of the pupil and later dilatation. An early symptom of paralysis also is the failure of the pupil to respond to light, sometimes remaining widely dilated even when exposed to the most intense illumination. Another symptom of the same class of which cognizance should be taken is the development of strabismus from the involvement of the nerves previously mentioned.

Constipation as a rule is often obstinate and especially so towards the end of fatal cases, while if diarrhea be present or the bowels be normal, brain abscesses and meningitis may with a certain degree of assurance, be eliminated. Occasionally, in rare cases, paradoxical symptoms may be present, as slow pulse, aphasia, agraphia, impairment of memory and progressive emaciation, these cases, however, are of a very chronic type and the exact intracranial lesion may only be determined when the case comes to autopsy. In adults, of course, it is possible to differentiate the symptoms of the intracranial complications from that of the mastoiditis, but in children such is not always the case and a meningitis may be fairly well under way before more prominent symptoms become evident.

The pathological changes taking place in the dura vary in their rapidity with the extent of the preliminary infection and from at first being slightly reddened and dull in appearance, the membrane will pass through the successive degrees of vascularity until it becomes thickened and studded with granulation tissue. In the chronic cases dependent upon a circumscribed area of necrosis or caries of the underlying mastoid process, it becomes black in color like the bone, softened and gangrenous, while the parts are bathed in serum and pus and may later perforate producing a diffuse leptomeningitis. Where the destruction of the osseous tissue is accompanied with considerable pus formation, the dura is separated from the bone by a collection of purulent débris, varying in color from the creamy pus of the acute cases to the thin, discolored material in the more chronic forms. As pointed out by Zaufal, in the very chronic cases, the dura may be enormously thickened and present a fibrous or sarcomatous appearance. In one case coming under his observation, the dura being three-fifths of an inch thick.

The late development of basilar meningitis following a previously localized area surrounding a

temporo sphenoidal abscess was well illustrated in the following case:

R. L., female, eighteen years of age, had measles in infancy followed by a suppurating ear for several years. The discharge then ceased for a time, but would make its appearance in small amounts whenever she had an attack of coryza. Four months before she came under my observation the impairment of hearing became markedly worse and a scant foul discharge was constantly annoying by keeping the canal moist. A few weeks later pain began to develop in the aural region, but she stated that she could never definitely localize it with any degree of accuracy, but the slightest movement of the head and body would immediately render it much more intense. On examination, she was in an apathetic state and cerebration appeared to be very sluggish. There was sensory and motor aphasia, marked drooping of the eyelid and the left pupil was dilated, evidences of optic neuritis on this side being well marked. There was a large perforation of the membrane surrounding the umbo and a smaller one in the flaccid membrane. The temperature was 98.2° while the pulse was but 64. Under ether anesthesia the radical mastoid operation was performed and great quantities of blackened necrosed bone and foul pus were removed from the region of the antrum and inner wall. The cortex of the mastoid showed a condition of compactness almost approaching eburnation and was removed to reach the softened areas, with the greatest difficulty. As evidences of cerebral abscess were more prominent even than the mastoid symptoms, an independent trephine opening was made in the skull over the temporo sphenoidal lobe and the dura immediately presented, as in the previous case, as a red, non-pulsating mass. An opening was then made in the inflamed membrane and after considerable difficulty about one-half ounce of pus was evacuated. Considerable improvement was evident in her condition for twenty-four hours, when the temperature ran up to 105°, the pulse became erratic and bounding, varying from 70 to 120, while intense pain was complained of over the entire head, but especially on the left side, where all her trouble had been. The symptoms of purulent meningitis rapidly increased and she died in coma two days after the operation. An autopsy was refused.

The serious aspect of the intracranial complications of mastoiditis renders an early diagnosis of the pathological process present in a given case of supreme importance, and the differentiation of any symptoms indicating a beginning meningitis must, of necessity, be made early in the disease to allow the patient the greatest benefit from operative treatment. The chief symptoms of meningeal irritation are headache, occasional nausea, vomiting, vertigo, moderate increase of temperature and some acceleration of the pulse rate, while thirst, anorexia and constipation are mostly complained of, but are not characteristic. Percussion of the skull affords but little evidence as it may be either painless or painful above and behind the auricle. The differentiation between meningeal irritation and true meningitis in my experience being almost impossible, although the latter may be recognized when the headache becomes persistent and is followed by the group of symptoms above mentioned with, in addition, drowsiness, delirium and stupor, while the pulse at first accelerated, later becomes retarded.

The confusion of the symptom-complex may also be greatly enhanced by the primary stages of the meningitis being due to the congestion and edema of the surrounding parts. An interesting case has been reported by Knapp of aural suppuration with headache, nausea, dizziness and some stupor. Later the mastoid became swollen and tender, and an opening an inch deep was made, but no pus was found. Four days later free suppuration occurred, both from the opening and the canal, and temporary relief was obtained. The grave symptoms, however, returned, with a rise of temperature to 105° and death occurred. The necropsy showed a purulent leptomeningitis of the left temporal lobe and lateral ventricle, while pus was on the inner side of the mastoid, in the attic and especially around the foramen lacerum.

The great difficulty in recognizing the condition is also graphically shown by another case of the same author's of an apparently strong, healthy man, with purulent otitis for three years. The discharge had ceased for one week and there had ensued headache, increase of temperature, drowsiness, stupor, movements of hands, incoherent and difficult speech and delirium. One physician made the diagnosis of a partial meningitis, while three others considered the condition as one of otitic cerebral abscess. The mastoid was sclerosed and under the cortex the osseous tissue was blackened in patches and contained a few small cavities filled with thin pus, while more deeply, the bone appeared healthy, hard and ivory-like, and free from caries or necrosis and gave no clue to the way by which the infection might enter the cranial cavity. The patient died three days later and the autopsy disclosed an extensive tuberculosis of the lungs, pleura and pericardium and a tubercular meningitis which had no connection with the ear.

The difficulty of diagnosis is also enhanced when the otitic meningitis occurs in a tuberculous, nephritic or diabetic individual and a careful survey of the past and present history of the case may even then fail to establish the identity of the affection. As an operation would be more successful if the diagnosis was successfully made before opening the cranial cavity, an exploratory operation may in selected cases be advisable, but usually it is often useless and sometimes it may be dangerous, as it may hasten the unfavorable termination of prexisting lesions, or even induce the formation of new ones.

Aside from the localizing symptoms which are of great value when present, the chief symptoms indicating an intracranial lesion have already been mentioned and the comparative worth of the

different symptoms is of great value in determining the presence or absence of meningitis. Optic neuritis is a symptom of great value, but is less frequent in meningitis than in brain abscess. Headache is very intense in leptomeningitis, although it may be absent in some cases. Slowness of the pulse may be an important symptom of incipient meningitis, but unfortunately it is often not characteristic. Rigidity of the mucha is seen in many conditions and depends upon divers causes, so that it is not characteristic of meningitis, although in connection with other symptoms I consider the rigidity of this region as of considerable diagnostic import. Vertigo and nausea may exist in any of the intracranial complications of mastoid empyema, while fever when high and persistent is strongly indicative of a purulent leptomeningitis, although Allport reports a case of influenza followed by mastoiditis, sinus thrombosis, meningitis and death in which as a most remarkable feature, was the continued presence of a subnormal temperature. The patellar and other reflexes afford little aid, although they are generally absent in meningitis.

The most reliable group of symptoms characteristic of meningitis in adults are in connection with the preceding history, constant high temperature, headache and vomiting. But at the same time any intercurrent acute affection must be excluded and the diagnosis is of necessity rendered much more difficult in children, since any acute affection and even an attack of gastro-enteritis may for a time produce symptoms very similar to those of meningitis.

Finally, lumbar puncture may in case of doubt, afford much valuable information. Grunert in two cases obtained positive results in suppurating leptomeningitis of otitic origin, while Gradenigo used the method in two cases with brilliant results and as under aseptic precautions Quincke's method offers no especial dangers to the patient, it may in certain cases be the only way left to ascertain the presence or absence of pus in the cranial cavity.

It is necessary in this connection, however, to constantly bear in mind in these cases, that it is rare to have but one complication, as two, or even three, viz., abscess, meningitis and sinus phlebitis, may all be present in a fatal case. The exact condition cannot be accurately known until an autopsy is made, but even when such is the case, a careful study will enable one in a limited range, to distinguish the most prominent affection. Such a case has been reported by Knapp, in which necropsy showed mastoid empyema, perforation of the lower mastoid wall and extension of the pus down the neck, with epidural abscesses in the middle of the posterior cranial fossa, septic thrombosis of all the sinuses, of both internal jugular and most of the cerebral veins with in addition an abscess in the temporosphenoidal lobe and cerebellum and diffuse purulent meningitis.

With a better appreciation of the relative value of the symptoms and a constantly improving surgical technic the prognosis of meningitis following mastoid empyema affords considerable hope, especially as favorable results have followed prompt diagnosis and early surgical relief. Macewen having reported six recoveries in itself proves that a lethal issue does not always ensue. In the majority of instances, however, secondary purulent meningitis is rapidly fatal, especially so in patients under ten years of age, so that as a rule it may safely be said that the younger the patient the more likelihood there is of a fatal termination.

In the early stages of meningitis and for but a short time only, ice caps to the head and large doses of bromides to lessen irritability of the nerve centers may be tried in addition to free purgation, but these measures are of little value, and the only hope as regards success lies in the early institution of surgical measures. The earlier the operation is performed the greater the chances of success and as the disease is invariably fatal if not checked by operation, we should not hesitate to interfere even in apparently hopeless cases.

It is unnecessary here to describe in detail the various steps of the operative procedures, but the principles indicated are to perform the radical mastoid operation thoroughly and to take especial care to discover the site of any perforations into the cranial cavity. If such are found they should be enlarged and the brain cavity freely explored, but if, however, no sinus is found, or no area of necrosis suggestive of the site of the meningitis be found, the roof of the tympanum should next be explored by entering the cranial cavity above the meatus. The inner table may also require removal in the area of the mastoid wound and any focus of meningeal inflammation or pus cavity should be thoroughly cleansed, the parts packed and the usual dressings applied.

# MEDICAL PROGRESS.

## MEDICINE.

**Subcutaneous Nourishment.**—Repeated attempts have not been wanting to nourish the body by means of oil or fat injected under the skin and it is even believed by some that the resting body can be kept at a steady weight by combining these injections with rectal enemata. Experimental data are, however, wanting and it is held by others that the amount of fatty substance absorbed is really so small as to play no part in nourishment. H. Winternitz (Zeitsch. f. klin. Med., Vol. 50, Nos. 1 and 2) has approached this mooted question from an entirely different point of view. He injected iodized fats and could follow their course in the body by quantitative iodine determinations of the urine during life and of the organs after death. The results are very discouraging, for though iodine appeared in the urine very soon after injection, the excretion was so very small and was kept up for such a very long time, that absorption here must necessarily be a very slow process. Thus, several months were required before 500 grams were entirely taken up. Even the rectal administration of oil is more satisfactory, especially if pancreatic substance is added. Another disadvantage lies in the fact that multiple injections are necessary at each sitting. A number of inoperable cases of esophageal and gastric carcinomata steadily lost weight with this method of nourishment and in some, deposits of unabsorbed fat were found under the skin after death.

**Normal State of the Cardia of the Stomach.**—The researches of D. Sinnhuber (Zeitsch. f. klin. Med., Vol. 50, Nos. 1 and 2) prove that the cardia of the stomach is normally in a condition of tonic spasm. This is increased by the muscular fibers surrounding the esophageal opening of the diaphragm and by the oblique entrance of the esophagus into the stomach. The spasm is the result of two forces acting in an opposite direction: the one contracting and the other relaxing. The former is particularly localized in the region of the cardia or the cardia itself, the latter is conducted from the medulla oblongata through the vagi to the cardia. Division of the vagus above the diaphragm leads to relaxation of the cardia, while division high up, especially when the right inferior laryngeal nerve is not injured, will bring about a temporary increase in tone.

**Origin of Urobilin in the Stomach.**—Urobilin is sometimes found in acid gastric contents and A. Braunstein (Zeitsch. f. klin. Med., Vol. 50, Nos. 1 and 2) is of the opinion that it is of intestinal origin just like the urobilin in the bile itself. A high acidity of the stomach contents is not necessary, unless bile rich in urobilinogen has regurgitated into the stomach. This regurgitation must, however, take place through the bile and need not remain in contact with the gastric mucosa long before the test becomes positive.

**Histogenesis of Lymphatic Leucemia.**—The underlying cause of lymphatic leucemia is an increased proliferation of lymphocytes in the lymphnodes. It has always been a question how these cells reach the blood-stream until it was shown, that this takes place, to some extent at least, via the lymphatics. M. Mosse (Zeitsch. f. klin. Med., Vol. 50, Nos. 1 and 2) also examined the vessels and found aggregations of cells around as well as within the vessel-walls. He could not, however, decide whether these cells reached the blood-stream passively or by virtue of their own ameboid motions.

**Hemorrhagic Infarction of the Lung.**—The careful examinations of E. Tiedmann (Zeitsch. f. klin. Med., Vol. 50, Nos. 1 and 2) upon lung infarcts are based upon the study of a large pathological material. They are generally peripheral and wedge-shaped with the base directed toward the pleura so that a prominence is formed. In size they vary considerably; they may be very small and multiple or so large as to involve an entire lobe of the lung. Percussion will give dulness over a circumscribed area of the chest but sometimes there is also a tympanitic note due to the surrounding edematous pulmonary tissue, the air in the bronchi, which is set into motion, or the loss of tension within the immediate neighborhood of the infarct. Mistaking the latter for a tuberculous lesion is hardly probable since the position of the two conditions differs. Further physical signs are, on palpation the vocal fremitus may be increased, or, if the infarct is very voluminous, diminished; on auscultating we often hear neither respiratory murmur nor adventitious sounds except in the earliest stages. If râles do occur, these are pleural or bronchial in origin, or else are transmitted from the surrounding alveoli, and bronchial breathing is not rare since the solid tissue transmits well the bronchial sounds. Bronchial râles are also well propagated where a bronchitis exists. In most cases examined the infarct was situated in the right lower lobe; in only one case was the apex involved. The diagnosis is often rendered very easy by the presence of an endocarditis or nephritis and by the clinical symptoms.

**Observations on Leucemia.**—P. Reckzeh (Zeitsch. f. klin. Med., Vol. 50, Nos. 1 and 2) has had the rare luck to observe seven cases of leucemia, including chronic lymphatic and mixed types, and one complicated by a pernicious anemia. All the patients were males; a history of trauma to the splenic region could be elicited in three, while in the others rheumatism, nervous influences and malaria probably played an important rôle. In the traumatic cases the onset was more or less sudden. The following symptoms deserve mention: Initial hemoptysis and enormous hemorrhages from the nose, fever due to constipation or complications, albuminuria, edema and ascites in the later stages, very marked swelling of the spleen and lymphnodes; dyspnea, due to complicating pleurisy or pneumonia or secondary to pressure of lymphnodes on the bronchi; catarrh of the intestinal tract and marked tenderness of the bones. The characteristic blood-changes were found in all cases. In order to setttle the question of migration of lymphocytes, the author several times applied cantharidal plaster to the lymphatic cases, but only leucocytes were found in the resulting blisters. The pus from a small acne pustule examined was also free from mononuclear cells. Where a pernicious anemia complicated the disease, this was probably secondary from the profuse leucemic hemorrhages. In one case pilocarpine was tried extensively without either good or bad effects. In conclusion, a case of pseudo-leucemia with extensive metastases and one of generalized lymphatic tuberculosis are reported.

**Marked Hemorrhagic Diathesis Complicating Jaundice.**—The case reported by E. Fabian (Deutsch. Arch. f. klin. Med., Vol. 77, Nos. 1 and 2) is exceptional from many points of view. A patient, forty-four years old, was suffering from chronic ob-

structive jaundice with attacks of colic for many years, so that gall-stones were surmised with certainty, but the autopsy revealed caseous tuberculous lymphnodes at the porta hepatis which had completely destroyed the common duct. The direct cause of death was an uncontrollable hemorrhage from almost all the mucous surfaces of the body. The most interesting bleeding was that from the bronchial mucous membrane; for several days before death, the patient became cyanotic and dyspneic in attacks and then voided perfect casts of the bronchial tree, showing clearly the subdivisions of second and third order. These casts consisted solely of clotted blood.

**Circulatory Disturbances in Acute Infectious Diseases.**—It has already been proven that collapse in infectious disease is caused by exhaustion of the vasomotor system. PÄSSLER and ROLLY (Deutsch. Arch. f. klin. Med., Vol. 77, Nos. 1 and 2) have repeated the experiments with improved methods, in order to ascertain what part the heart itself plays in the process. The conclusions were in the main the same, since it was found that the heart is in no way responsible for the lowering of blood-pressure. Quite on the contrary, in pneumococcus and diphtheria infection at least, the heart compensates for the vascular paralysis, by increased work. Whatever weakening of cardiac action eventually occurs is to be ascribed to insufficient circulation in the heart muscle itself from lowered arterial tone. In diphtheria alone, a diminished resistance on part of the heart was noticed, which might develop into complete cardiac paralysis after prolonged action of the toxin. This corresponds with the fact that anatomical lesions are more often found in the heart after diphtheria than after other infections.

**Visceral Syphilis.**—Occasionally intra-abdominal gummata have peculiar locations so that wherever an extraordinary symptom-complex presents itself, syphilis must be carefully considered. The same holds true for common complaints such as gastric ulcer and cholelithiasis, which do not yield to the usual treatment, especiallly if the patient gives a history of a venereal sore. H. QUINCKE (Deutsch Arch. f. klin. Med., Vol. 77, Nos. 1 and 2) mentions several interesting cases from his own extensive practice. In one, marked dilatation of the stomach with all its concomitant symptoms developed and while lavage and diet brought about some amelioration, a real improvement was noticed only after inunctions and iodides. The patient died later of some other cause and at the autopsy the duodenum was found compressed by the remains of a retroperitoneal gumma. In a second case the gummata were located more posteriorly and the liver was the seat of an interstitial process. The correct diagnosis was made during life but only because there also was a motor disturbance in the larynx. Cases III and IV closely simulated cholelithiasis since there was gummatous induration about the biliary passages. Stress is then laid upon the syphilitic mesarteritis which underlies so many aortic aneurisms; in two cases an antiluetic treatment brought about considerable improvement and almost complete disappearance of physical signs, while in a third a compression of the subclavian artery was materially benefited. In conclusion, three interesting cases of brain-syphilis are recorded: the first presented the symptoms of a meningitis with implication of both facial and acoustic nerves or their nuclei; in the second there was also bilateral deafness with right-sided facial paresis, while the last was remarkable on account of its subnormal temperature: the lowest record was 90° F. on the day before death.

**Oxyuris Vermicularis.**—Anybody who will take the trouble to hunt through text-books, will encounter many contradictory views concerning the common thread-worm. This has led A. HELLER (Deutsch. Arch. f. klin. Med., Vol. 77, Nos. 1 and 2) to give a brief account of the peculiarities of this parasite. Its entire life-history takes place in one host. As soon as a ripe egg reaches the stomach, the worm will break through the shell at a certain more prominent place near the head of the egg. The free embryo at once migrates into the duodenum, where it goes through all its phases of development until ready for reproduction. This latter process takes place in the cecum and the vermiform appendix, where the largest number of egg-bearing female-parasites are regularly encountered. The eggs are then deposited in the further downward course, upon the mucus secreted in the colon and rectum and in the moist secretion of the anal fold. Auto-infection is the rule, for since the itching is severe the patients will infect their fingers from where the worm eventually gets back to the stomach. An examination of the finger-nails of persons afflicted invariably shows the presence of eggs and even of young worms. The treatment is simple but must be carried out conscientiously. Calomel is first given, since this removes mucus which is so essential as a breeding place; this is followed up by santonin and large enemata containing 0.2 to 0.5 per cent. soap. After eight days the cure may be repeated. Care should be taken that no affected member of a family goes untreated, since one may reinfect all.

**The Value of Agglutination in the Diagnosis of Typhoid.**—That the value of agglutination phenomena for the diagnosis of infectious diseases is much more complicated than was assumed by earlier authors, is the conclusion arrived at by H. STERN (Berl. klin. Woch., July 27, 1903), from a study of late observations. The increase in the degree of agglutinative action of the blood serum in the presence of the typhoid bacillus, beyond the limits which characterize the non-typhoid sera,—that is in a dilution of 1 to 50 during a two-hour exposure and microscopical observation—cannot at the present time be taken as a certain indication of a present or past typhoid infection. Numerous investigations within the last years have shown that the blood serum of an organism, which has been infected by some specific germ, not only exhibits agglutinative properties in the presence of this particular bacillus, but also reacts in the presence of related varieties. It has even been proved that various proteus and staphylococcus species have also become agglutinated in the presence of the typhoid bacillus. The difficulty remains therefore of distinguishing between a direct and an indirect agglutinative action. Serum diagnosis cannot therefore at present give proof of the true causative factor in an infection—it only indicates the probable source, and the probability is changed to certainty in proportion to the degree of agglutinating power which the serum displays. It seems proper, therefore, not to speak of a positive or a negative Widal reaction, but simply to state that fact, that is to say, the approximate limits observed with the bacterial varieties in question. The reaction is not one which is restricted to one species, but is characteristic of certain constituents of the bacterial cell.

**Nocturnal Incontinence and Adenoids.**—Apropos of two cases in which ablation of adenoid vegetations at once checked nocturnal enuresis of years' standing, U. MELZI (Gazz. Osped., July 12, 1903) reviews the various theories as to the relationship between the presence of adenoids and incontinence; and concludes that whatever may be the pathogenesis of enuresis in adenoid patients, the fact remains that in a large proportion of cases, extirpation of these vegetations does cure nocturnal enuresis; and in the treatment of the latter condition, the possibility of adenoids as an exciting cause should always be borne in mind.

## SURGERY.

**A New Operation for Puerperal Mastitis.**—The disadvantages of the usual, radiating incision, are the long time required for closure of the wounds and the deformity which usually follows. E. Hopmann (Centralbl. f. Chirurgie, Aug. 1, 1903) now makes a semicircular incision around the lower half of the breast, dissects it bluntly from the fascia of the pectoralis major and then incises the abscesses widely from behind forward and from the center to the periphery. The drainage tubes will then lie in the most favorable position so that they can be removed in the majority of cases in fourteen days. The scar will be covered by the pendulous portion of the gland and will hardly be noticeable. Deep abscesses which can not be opened without very deep incisions from in front are also rendered easy of access. A similar operation is recommended for the extirpation of enlarged prepatellar bursæ.

**Spear Wound of the Heart.**—A most interesting example of this condition is described by T. McArdle (Jour. R. A. M. C., Vol. I, No. 2), where a barbed spear was embedded in the chest, passing through the wall of the left ventricle, but without entering the cardiac cavity, and the patient made a good recovery after operation. The patient was a Soudanese, and the spear entered near the lower angle of the left scapula, passed through the chest and projected at a point midway between the left nipple and the midsternal line, about one inch above the nipple. Operation was done. A part of the sixth rib was resected and the spear was found to have penetrated the margin of the left ventricle. This fleshy fragment was divided, the spear withdrawn and the external wound sutured. Restoration of pulse and respiration followed and the man made an uninterrupted recovery. Interesting points are the slight general influence produced by operative interference with the cardiac muscle, the profound disturbance caused by the change in cardiac position, as shown by the apparent fatal syncope which followed traction on the spear while it was still fixed in the wall of the heart, and the peculiar modification of the cardiac sounds produced by the presence of a foreign body in the cardiac wall.

## NEUROLOGY AND PSYCHIATRY.

**Protracted Alcoholic Delirium.**—It is necessary to distinguish this delirium from the acute alcoholic psychoses on the one hand, and from chronic alcoholic paranoia on the other. Protracted alcoholic delirium, according to S. A. Suchanoff and I. N. Vedensky (Roussky Vratch, No. 28, 1903), is observed in persons who have been addicted to alcohol for a very long time, and who have formerly undergone several attacks of delirium tremens. The first symptoms are those of auditory hallucinations and illusions; he hears "voices" which are accompanied by noises in the head and ears; the patient fully appreciates his condition, and is even able to refer to it in somewhat doubtful manner. These auditory hallucinations are of a variable degree of intensity and form. He is cursed for his alcoholic excesses, or he hears some one defending him from maligning enemies; or the hallucinations are of an intensely blasphemous character, etc. In severe cases the patient gradually loses the appreciation of surrounding conditions, and therefore asserts the stronger his belief in the reality of the hallucinations. However, notwithstanding the prolonged character of the affection there is usually no marked inhibition of mental powers, and the "voices" gradually lose their significance. The majority of such patients are thus able to keep out of asylums, and even attend to their ordinary occupations, except, of course, such of them as are prevented by the "voices." A great many of the patients become total abstainers after certain threatening symptoms. Chronic alcoholic paranoia is distinguished from protracted alcoholic delirium by the fact that in the former there is a definite persecution mania, which is often manifested in violent outbreaks. As contrasted with the alcoholic's good-nature the paranoiac is suspicious, quarrelsome and often dangerous. The course of the disease in paranoia is progressive, while under favorable circumstances the alcoholic rapidly improves, and is soon convalescing. Psychically the paranoiac may soon become demented, and, of course, disabled from attending to any kind of work, while the alcoholic's mentality suffers but little. In alcoholic melancholia, which may sometimes be confounded with protracted alcoholic delirium in its early manifestations, there is a condition of depression and despair; the patient is frightened, morose; he suffers from threatening auditory hallucinations of a terrifying nature; he seeks isolation, is unwilling to converse with anybody, etc. Of the cases observed (out of 4,813 insane patients there were 33 with protracted alcoholic delirium) 30 were men and 3 women. Twenty were tainted by alcoholic heredity, 3 by nervous and mental affections of relatives, and in general the hereditary influences could be traced in 96.55 per cent. of the cases. The very great majority—fully 88 per cent.—belonged to the illiterate class of the community, including, among others, agricultural laborers, factory workers, etc.

**Idiopathic Contractions of the Right Arm.**—The patient had been suffering for the last three months with clonic, lightning-like convulsions that would occur 25 to 50 times per minute. They begin by an abnormal movement of the right shoulder joint, whereby the scapula rotates somewhat around its horizontal axis, and the joint is slightly raised, while the head is turned back and the chin to the side. This is followed by a maximum pronation of the forearm and the close approximation of same to the trunk. The hand then drops down to the sexual organs or continues its motions toward the left axillary region, and is then drawn forcibly (by the patient) backward and downward. This cycle of movements which is extremely painful and renders the patient very miserable, ceases only during the sufferer's sleep. Outside of great physical exertion Vershubsky (Prakt. Vratch, No. 27, 1903) failed to discover anything in the patient's past history that would give him a clue to the etiology of the condition. He was compelled to exclude, through the absence of the necessary factors, toxic influence, psychic states frequently characterized by localized convulsions, such as cortical epilepsy, and others; organic disease of the nervous system, as, for instance, tumor of the brain, was excluded by the absence of any other symptoms, etc. Of the functional nervous disorders, the affection did not resemble hysteria, epilepsy, chorea, paralysis agitans, or any of the tics. The only similar disease which could be supposed in this case would be paramyoclonus multiplex; but in this the muscular contractions do not embrace whole groups of muscles, and, moreover, the muscles affected are usually symmetrically disposed, which was not the case in the patient under observation. It thus remained for the author to designate the case as one of idiopathic contractions. As regards the treatment of the condition, it is of interest to observe that neither drugs nor psychic therapy seemed to produce any effect. Not even hypodermic injections of duboisine sulphate, of marked utility in many similar conditions, were of any avail here. It was then decided to place the patient in the hospital with the possible view of operating, when in the course of a few days amelioration showed itself, and in about two weeks patient was discharged

considerably improved. However, as the improvement did not last long, and the patient insisting on anything being done to relieve him, operative interference was finally decided upon. The operation consisted in the separation of the tendons of the various muscles involved in the convulsive seizures. The convulsions ceased entirely during the first three days after the operation, but later on the contractions were renewed though not with the former severity.

**A Definition of Epilepsy.**—Idiopathic epilepsy is the real and original epileptic condition, and should be separated from Jacksonian, traumatic and other so-called forms of epilepsy. This distinction is drawn by J. W. WHERRY (Am. Med., Aug. 15, 1903) and from his own observations and the reports of other observers, he defines epilepsy as a state of autoasphyxia or a condition of physiological strangulation or suffocation; except that the cause manifests itself through obstruction to circulation rather than to respiration, though the ultimate effect in both cases—depriving the brain of oxygen—is the same. Several observers have noted that convulsions have followed hanging, which were similar to those of epilepsy. Convulsions as a physiological process, can usually contend successfully against a physiological cause, as in epilepsy, and it contends with equal vigor, though with less success, against a mechanical one, but in each instance it arises in the same chemic way, from similar conditions, and in both cases it is introduced for purposes of relief. The convulsion therefore arises from a condition of asphyxia, which has its birth in a vasomotor spasm. If the latter could be explained, the author believes that the long-sought cause of epilepsy would be revealed.

## PHYSIOLOGY.

**Contribution to the Study of Spinal Reflexes.**—In the investigation of the spinal reflexes of the European turtle, G. FANO (Archives Italiennes de Biologie, June 10, 1903) was led to recognize marked oscillations in the excitability of the spinal centers, and to suppose that these oscillations are caused by the conflict between inhibitory and automatic actions. He also established the influence exerted by these variations upon the manner in which an animal reacts to external stimuli. It follows from his research that the internal work of the voluntary centers, in acting upon the bulbar functions, so far as it does not express itself in external movements, is revealed as an influence upon the functional capacities of the nervous centers and contractile tissues, which influence, if not having a metabolic basis, might at least be classed among the trophic functions, and which evidently has some effect upon voluntary as well as reflex actions.

**Destructive Ferments in the Animal Cell.**—A contribution to the question as to whether the animal cell secretes a ferment which is capable of destroying sugar is made in the form of a preliminary communication by I. FEINSCHMIDT (Fortschritte der Med., Aug. 1, 1903). He was able to secure from fresh pancreas, liver and muscles, by means of a Buchner press, a fluid which rapidly disintegrated sugar—care being taken that the procedure was carried out with all precautions as to sterility. The addition of small amounts of chloroform sterilize the fluid but do not interfere with its glycolytic powers. The latter are interfered with, however, by the addition of larger quantities of antiseptics. In the presence of hydrogen gas the glycolysis was more marked than in ordinary air. During the process there is produced, carbonic acid, alcohol and various other acids. Fermentation in most cases did not begin until some three to six hours. The author was able to isolate the ferment from the fluid by means of ether and alcohol, and in comparing the two, he found that if the ferment alone was mixed with the sugar, the reaction came on quicker and was more marked than if the fluid itself was employed.

**The Physiological Action of the Proteoses.**—It is well known that the products of proteid digestion, when injected directly into the circulation, exert various toxic effects, among which are the abolition of the coagulability of the blood, and changes in its reaction and composition; an acceleration of lymph-flow; a fall in arterial pressure; anuria; deep narcosis, and other toxic symptoms, as well as a certain degree of immunity toward subsequent injections. F. P. UNDERHILL (Am. Jour. of Physiol., Aug. 1, 1903), under the auspices of the Rockefeller Institute, conducted a series of new investigations in this field, which overthrow the conclusions obtained by Pick and Spiro, who maintained that it is possible to obtain by proteolysis (*e.g.*, by trypsin, autolysis, alkali; with casein and edestin by acid also) typical albumoses and peptones which fail to show any influence upon blood-pressure when they are injected into the blood; and even the typical active products prepared by acid or pepsin-acid methods, lose this activity by a relatively harmless purification (treatment with alcohol) without undergoing a change in chemical character. Underhill's researches lead to the conclusion that there is at present no occasion for attributing the physiological effects following the injection of proteoses into the circulation to the presence of contaminating substances derived from animal tissue or elsewhere. Typical purified vegetable proteids which, when injected, are inert in this regard, yield on hydrolysis with acids, or even water alone, proteoses which provoke the characteristic reactions. The proteoses which are formed by the action of proteolytic enzymes of vegetable origin (bromelin, papain) or purified proteids, likewise alter in vitro the coagulability of the blood and call forth the other well-known symptoms of proteose injections. The proteoses occurring in nature in the vegetable kingdom are similarly active, as was to be expected if the toxic properties are a function of these products per se. No method of "purification" has been found which will deprive proteoses of this characteristic behavior in the circulation; when the chemical make-up of the proteoses is profoundly altered and they lose their chemical identity, the typical physiological action may also be lost. The author regards the failure of other authors to obtain toxic products by hydrolysis of proteids with acids, etc., as attributable, in part at least, to the fact that they injected mixtures of unknown composition and probably containing either insufficient doses of proteoses proper, or antagonistic compounds simultaneously present. Different animals vary in their susceptibility to the toxic action of injected proteoses, the rabbit being extremely resistant. There is at present no reason for denying the existence of many chemically unrelated substances which call forth apparently similar responses in the animal organism.

**The Nature of Rigor Mortis.**—Physiologists have generally attributed the onset of rigor mortis to the coagulation of the myosin contained in muscle. OTTO FOLIN (Am. Jour. of Physiol., Aug. 1, 1903) on the basis of his recent investigations, believes that this supposition is unwarranted. It was Kühne who first announced this hypothesis on the strength of the discovery that during rigor mortis the mother substance of myosin cannot be detected in the muscle. A serious obstacle to this view was the fact that rigor mortis, instead of being a permanent condition, gradually disappears, until Halliburton apparently explained it away by the statement that an enzyme, dissolving the coagulated myosin, thereby terminates the causation of rigor.

Folin brought about an artificial rigor in frogs' muscles by cooling them to —7° to —15° C. The muscles did not lose their translucency, which fact argued against any coagulation of part of the muscle having taken place. Moreover, on chemical examination of the muscle which had passed into rigor, performed by mincing the muscle, extracting the plasma by squeezing it and then heating the expressed plasma, the author found that the coagulum formed equaled in bulk the coagulum obtained in a similar way from muscle which had not passed into rigor. He therefore concludes that rigor mortis must be explained, not upon a chemical, but upon a mechanical basis, and might be regarded as of the same nature as an ordniary contracture. Lending support to this view is the fact that muscles sometimes spontaneously go into a condition of contracture. Of related interest in this connection is the view advanced, in 1901, by A. Spingarn, who, in a series of investigations on the inhibitory phenomena connected with striated muscle, was led to believe that such muscle, in the absence of the proper inhibitory influences, has a constant tendency to pass into a condition of contracture, of which the contractures due to heat, death, cold, spontaneity, toxins (cornutin, veratria, caffeine) and disease (Thomsen's disease) are different forms.

**The Survival Excitability of Striated Muscle.**—That a frog's muscle may preserve its excitability for strong induction shocks thirty hours after death, as stated by Ernst Mangold (Pflüger's Archiv., Vol. 96, Nos. 9 and 10) is not new, but the further discovery that the earlier or later onset of rigor or its disappearance, has no regular influence on the excitability of the muscle, is of extreme interest. The author also discovered the surprising fact that if a muscle, either cut out of the body or left in situ, be allowed to pass into rigor while kept in a physiological salt solution, its excitability, which until the onset of rigor has only slowly diminished, now suddenly undergoes a rapid reduction, as if caused by the mechanical obstacle to its contraction. In the average case the excitability continued after the disappearance of rigor for two to six hours. In harmony with the law that seems to underlie so many necrobiotic and paralytic phenomena, the author found that previous to the fall of excitability there is a remarkable rise. The temperature of 10° to 12° C. preserves the excitability for a particularly long time. The response of muscle to electrical stimuli occurs after the power of response to thermal stimuli has vanished. Contrary to what one would expect, it was found that disease or hunger preceding the death of the animal, rather than diminishing the duration of survival excitability, markedly increases it. The muscles of an embryo-dog, including the diaphragm, reacted fifty-one hours after death, the prolonged contractions resembling those characteristic of veratrin poisoning.

**Insufficient Development of the Pectoralis Major Muscle, Absence of Nipple, Separation of Ribs, and Unusual Course of the Urethra—All in one Person.**—The patient's deformities were discovered through mere accident, when he applied to Zeiliger (Prak. Vratch, Nos. 26 and 27, 1903) with high temperature, general weakness and pains in several joints. The examination revealed entire absence of the right nipple and areola, and a general undeveloped condition of the right side of the chest as compared with the left; palpation demonstrated further that from the third and down all the ribs are free from any muscular layer, and are directly covered by the skin, so that the sternocostal part of the large pectoral muscle and the underlying pectoralis minor are absent. The right shoulder is raised, the right scapula is higher than the left, and there is slight scoliosis of the thoracic portion of the spine toward the right. There is also considerable asymmetry between the right and left sides of the chest. The examination of the penis revealed a very small opening in the lower portion of the organ in the sulcus retroglandularis, from which the urine flows in a small stream. Besides this hypospedia there was entire absence of the urethra in the portion of the glans penis. Physical examination of the lungs and heart elicited pulmonary cirrhosis of the right apex. Patient had also evidently suffered when a child from tuberculosis of the bones. The other portions of the lung show emphysema, which is evidently of a compensatory nature, as brought about by the ready pliability of the right half of the chest which became thinner because of the absence of a considerable portion of the pectoralis major muscle. It was also frequently observed that the lungs were, as it seemed, protruding though the thinned-out walls of the chest, which fact alone would be sufficient to account for the presence of an obstinate alveolar emphysema. Notwithstanding the physical disadvantages under which the patient—a hard-working peasant lad—labored, he was not to any appreciable extent disabled from attending to his ordinary every-day work, and as soon as he recovered from the attack of acute articular rheumatism for which he applied to the hospital, he returned to his work.

**The Hydrolysis of Fats by Means of Steapsin.**—That steapsin is capable of hydrolyzing (saponifying) fats outside the organism, is shown beyond doubt by J. Lewkowitsch and J. J. R. Macleod (Proc. of the Royal Society, July 8, 1903). A few months ago, the former showed that lipase in acting on cotton-seed oil produces hydrolysis to the extent of three per cent. On the other hand steapsin causes hydrolysis to a very great extent. This fact is of considerable physiological importance, inasmuch as the quantitative experiments have hitherto been made almost entirely on monobutyrin and simple esters. It is shown that steapsin is not capable of producing the reversible reaction which it was thought, reasoning by analogy, this enzyme might produce.

**The Adaptation of the Pancreas to Different Foodstuffs.**—A series of experiments were conducted by F. A. Bainbridge (Proc. of the Royal Society, July 8, 1903) in the hope of determining, firstly, whether the pancreas does adapt itself to different foodstuffs, as has been maintained, and secondly, by what means this adaptation takes place. When dogs are fed on milk the pancreas secretes a ferment, lactase, which is capable of inverting milk-sugar, although in dogs not fed on milk no such ferment is present in pancreatic juice. It appears, therefore, that the pancreas does adapt itself to different foodstuffs by modifying the composition of its secretion, at any rate as regards the enzymes. It is believed by Pawlow and others that this adaptation is carried out entirely by a nervous mechanism, and that a given food reflexly excites the pancreas to secrete a juice specially adapted for the digestion of that particular foodstuff. The same view has been adopted by Weinland, as regards the lactase of the pancreas. In the light of Professor Starling's work in "Secretin," it seemed much more probable that the adaptation was due to a chemical stimulus. Since lactase is normally present in the intestinal mucous membrane of adult dogs and is increased in amount by a milk diet, it seemed possible that lactase entered the blood stream from the intestine and was picked out by the pancreas and secreted. But the blood of a milk-fed dog was found to have no inverting action on lactose, nor did intravenous injections of extract of the mucous membrane of the intestines of biscuit-fed dogs cause any secretion of lactase in the pancreatic

juice. Consequently, the lactase of the pancreas is not taken up as such from the blood, but must be formed by the pancreas itself. Furthermore, the experiments show that the intestinal mucous membrane of milk-fed animals, injected into dogs not fed on milk, causes the pancreas to secrete lactase, whereas lactose or extracts of mucous membrane injected separately have no such action. In the present stage of this investigation no complete explanation of these results is offered. It seems probable that as a result of the action of the intestinal mucous membrane on lactose, some chemical substance is formed, which passes by the blood-stream to the pancreas, where it stimulates the latter to manufacture a specific enzyme—lactase.

**The Optical Activity of the Nucleoproteids.**—In a research conducted by A. Gamgee and A. C. Hill, it was discovered that hemoglobin is a dextrorotatory body, while the interesting histon-like albuminous substance globin, which is obtained by the splitting up of hemoglobin under the influence of highly diluted hydrochloric acid, is a normally levogyrous albuminous body. A. GANGREE and W. JONES (Proc. of the Royal Society, Vol. LXXI, No. 473) find, as they had suspected, that the nucleoproteids of the pancreas, thymus and suprarenals, are dextrorotatory albuminous compounds. When a nucleoproteid, by the splitting off of albuminous molecules, which in its original condition formed part of its more complex molecule, becomes converted into a nucleoproteid of the "nuclein" type, its specific rotation increases. It is legitimate to infer that all the nucleoproteids form a class of dextrorotatory albuminous substances.

**The Physiology of Fertilization, Parthenogenesis and Development.**—In the course of a research undertaken to discover the substances in the egg that attract the spermatozoon, A. SCHÜCKING (Pflüger's Archiv, June 16, 1903) obtained many interesting results apart from the original inquiry, namely, as follows: In certain echinoderms the acid-reacting mass of eggs exerts a deadly, on brief exposure a paralytic, and when present in small amount, an agglutinating and attracting action on the spermatozoa of the same or of other species. The acid reaction of the extract of the egg mass with its mucous envelope is caused by the presence of primary potassium and sodium phosphate. On dialyzing this extract it is found that the non-dialyzable portion left behind contains the agglutinating substance. The egg extracts cause the same physiological effects upon the spermatozoa as the eggs themselves. The forerunners of fertilization are partly of a mechanical and partly of a chemical nature. The agglutination of the spermatozoa is brought about by the cooperation of the agglutinating substance in the egg with a special agglutinative substance in the spermatozoon. This phenomenon requires the presence of a certain amount of sodium chloride. It lasts only a short time for the compounds of agglutinin and agglutinated substance dissolves in water and cannot be again isolated. The spermatozoon does not bore its way into the egg, as commonly accepted, but its protoplasm melts into the protoplasm of the egg with the formation of a hyaline excrescence. Surrounded by the latter, the spermatozoon is drawn into the egg. The so-called disappearance of the vitelline membrane is not associated with the formation of a new membrane. Even when the protoplasmic mass appears homogenous, the vitelline membrane is present. It presents a meshy or sieve-like structure being pervaded with the finest of protoplasmic threads. During fertilization there is an interlamellar splitting of the vitelline membrane occasioned by the absorption of water. The increase in size by this absorption is considerable, being not seldom one-third of the volume of the egg. The beginning of the development of the entire ovum is rendered possible by the absorption of water. In the case of the echinoderms studied, in other species and also in man, the spermatozoa show in their penetration of the egg, in individual instances, certain central bodies, which occasion the union of the protoplasm of the spermatozoon with that of the egg. There is no violent penetration of the spermatozoa. Fertilization finds its analogy in the conjugation of the infusoria. The interlamellar splitting of the vitelline membrane is commonly said to protect the egg against polyspermia. But this splitting also occurs in polyspermia if the protoplasm of the egg is damaged by external agencies. The functions of the tail of the spermatozoon are to bring the head to the periphery of the egg, to mechanicallly stimulate the protoplasm threads of the egg by means of the movements of the head, and thereby to bring about union with the protoplasm of the egg. Fertilization may also be brought about by tailless spermatozoa, provided these be brought into intimate contact with the egg. Eggs that are stimulated by means of external agencies offer resistance to osmotic influences. If placed in distilled water, eggs remain for a period of time amounting to several minutes, longer capable of life and fertilization than other eggs. This observation, together with that of the absorption of water in parthenogenetic development, gave the key to the solution of the problem of artificial parthenogenesis. This latter can be brought about by the most widely variant stimuli—chemical, thermic, electric and light stimuli. Following the period of stimulation there is a period of relaxation, during which the water that is absorbed can start the processes of development. Even the direct addition of water in such a manner that the eggs may remain in distilled water for one minute and thereby be allowed to swell up, start parthenogenetic development. The best results were obtained by the use of acetic acid, in the concentration of one to two drops in 200 gms. of sea-water, acting for a period of forty minutes. Also sodium bicarbonate is capable of initiating parthenogenesis.

**Salivary Digestion in the Stomach.**—The evidence that the action of ptyalin is inhibited in the stomach soon after the ingestion of food is inconclusive, according to W. B. CANNON and H. F. DAY (Amer. Jour. of Physiology, Aug. 1, 1903). The support for this evidence from the commonly accepted accounts of mixing currents in the stomach is not well founded. Observations show that in many animals, including man, gastric peristalsis occurs only in the pyloric end of the stomach; the cardiac end remains undisturbed by the waves. Food in the pyloric end is soon mixed with the gastric secretions, but food in the cardiac end of the stomach is not mixed with the acid gastric juices for two hours or more, and in this region, therefore, during that time salivary digestion may go on undisturbed. Examination of the dried contents of the pyloric and cardiac portions of the stomachs of cats, after carbohydrate food mixed with active saliva has been given, shows that the percentage of sugar present is about the same in the two portions at the end of a half hour, and at the end of an hour the cardiac portions contains about 80 per cent. more sugar in unit volumes than the pyloric portion. The actual amount of sugar present in the fundus is relatively much greater than the ratio would indicate, for the fundus contains, after an ordinary meal, about five times as much food as the pyloric portion. After an hour the ratio of the sugar percentages in the two parts of the stomach begins to approximate unity again. This change is probably to be attributed largely to

diffusion of sugar from the fundus into the pyloric end, and to some extent to absorption. The diffusion of sugar does not to a marked degree remove the ptyalin from the food. Position does not very notably affect the differences in sugar production between the two parts of the stomach, although with the fundus lower than the pyloric portion, slightly more sugar is found in the fundus than when the opposite relation is maintained. When liquid food is given, when small amounts of foods are given, and when the stomach is massaged, sugar percentages in the two parts of the stomach are nearly the same. Mixing proteid with carbohydrate foods protects the ptyalin from the action of free hydrochloric acid in the relatively small pyloric part of the stomach and on the surface of the cardiac contents. The greater mass of the food, lying in the fundus, undergoes uninterrupted autolysis, not because the proteid protects the ptyalin, but because the food in this region is not mixed with the gastric juice. Much of the starch not changed to sugar is changed to dextrin, and thus, since dextrin is not readily fermented, the food is saved to the organism. The special value of this process lies in the fact that it occurs to the greatest degree in the fundus, in which region the hydrochloric acid, inhibiting the action of many of the organized ferments, does not for some time make its appearance. In the early stages of gastric digestion, if food has been properly masticated, the fundus serves chiefly for the action of the ptyalin; the pyloric portion, after a brief stage of salivary digestion, is thereafter the seat of strictly peptic changes. Later, after two hours or more, as the contents of the fundus become acid, the food in the stomach as a whole is subjected to the action of proteolytic fermentation.

**The Uniformity of the Pancreatic Mechanism.**—It has recently been pointed out by W. M. BAYLISS and E. H. STARLING that the secretion of pancreatic juice, which ensues on the introduction of acid into the duodenum or jejunum, is due, not to a reflex, but to the production, under the influence of the acid, of a substance (secretin) in the epithelial cells of the mucous membrane. This substance is at once absorbed into the blood vessels and carried by the blood to the pancreas, where it acts as a specific stimulus of the pancreatic cells. The same authors (Jour. of Physiol., Vol. 29, No. 2) find that the pancreatic secretin is not specific for each type of vertebrate animal, but is a simple substance of definite chemical constitution common to all types of vertebrates. On the other hand, in spite of certain assertions to the contrary, there is no doubt that it is specific in its origin and in its action. Apart from the increase of bile, which follows the injection of solutions of pure secretin, and may be direct or indirect, the direct action of secretin is limited to the pancreas. Of course, if a depressed effect is produced at the same time, one will get the usual effects of anemia of the medullary centers, amongst which salivation may be mentioned. Secretin is obtained by extracting the mucous membrane of the upper part of the small intestine with acid. From no other part of the body can secretin be obtained by a similar or any other mode of procedure. The authors tried in this way mucous membrane from all other parts of the alimentary canal, the salivary glands, the liver, spleen, pancreas, kidneys and tongue. They, therefore, conclude that prosecretion exists only in that situation where it is in a position to be acted upon by the acid chyme, and to discharge into the blood the body which shall act as the timely stimulus of the pancreatic cells.

**The Regeneration of Nerve Fibers.**—When certain precautions were taken, J. N. LANGLEY and H. K. ANDERSON (Proc. of the Physiol. Soc., Jour. of Physiol., Vol. XXIX, No. 1) found that in the sciatic and crural nerves, medullated fibers do not regenerate in the peripheral end of a cut nerve in 124 days. But medullated fibers may regenerate in the peripheral end without any connection being formed with the central stump; when such regeneration takes place the fibers degenerate on section of the nerves which run to the tissue surrounding the peripheral stump; *i.e.*, the regeneration which occurs in apparent independence of the central nervous system is not really independent of it. When the peripheral ends of two sensory motor nerves are joined, no contraction occurs in the muscles supplied by one of them when the other nerve is stimulated, but when the muscular branch of the crural nerve is cut, and allowed an opportunity of growing both into its own peripheral end, and into the peripheral end of the internal saphenous nerve, stimulation of the saphenous nerve may cause a reflex contraction in the muscles supplied by the muscular branch of the crural; this is still obtained after section of the crural close to the vertebra, so that it is to be considered as an axon reflex occurring in branching fibers which have grown down from the central end. When the central ends of two nerves are joined together, it is not found that stimulation of one gives a reflex by impulses passing up the other to the central nervous system; *i.e.*, apparently, union does not take place between the fibers, and neither nerve grows into the other. If a nerve is cut in a newly born animal, the nerve grows in length with the growth of the animal, although no union is formed between the peripheral and central ends.

**The Presence of Arsenic in Eggs.**—It has been maintained repeatedly by G. BERTRAND that arsenic, like carbon, sulphur and phosphorus is a constant constituent of the organsim. He now finds (Annales de l'Institut Pasteur, July 25, 1903) that all parts of the hen's egg contain appreciable quantities of arsenic, the yolk containing the greater part. In the 1-200 of a milligram found in one egg, from one-half to two-thirds is found in the yolk. The enveloping membrane contains almost as much arsenic as the white. These observations confirm the supposition as to the existence and the probable rôle of arsenic in all living cells.

## PEDIATRICS.

**Determination of Fat and Solids in Milk.**—To ascertain the relative accuracy of the simpler clinical methods of determining the fat, H. L. K. SHAW (Archiv. of Ped., Aug., 1903) compared five methods, judging the results by the absolute fat as extracted by solvents (ether, gasoline, etc.). In the Babcock test 17.6 c.c of milk are placed in a test bottle and 17.5 c.c. of sulphuric acid (sp. gr. 1.082) slowly added. These are mixed with a rotary motion, then centrifuged for four minutes. Boiling water is then added till the lower part of the column of fat comes within the scale on the neck of the test-bottle. It is again centrifuged for one minute and the layer of fat read off. The Gerber method proved to be inaccurate and clumsy, the Lefferman-Bean test troublesome and also inaccurate. The Holt cream gauge gives only approximate results and requires fresh milk in which the cream has not risen. The Marchand lactobutyrometer is a graduated tube into which 5 c.c of milk are put, a few drops of ten-per-cent. sodium hydrate solution added, then 5 c.c. ether and the whole gently mixed. When the mixture is homogeneous 5 c.c. of 93 per cent. alcohol is added, and carefully mixed. The tube is then immersed in a water-bath at 100° F. for fifteen minutes and the amount of fat read off from the scale. This is an easy method, but sometimes the milk coagulates when the alcohol is added. The extraction for standardizing

was made by Dr. Wheeler, chemist of the New York State Department of agriculture, by spreading the milk over absorbent paper, drying and extracting the fat in a Soxhlet apparatus. Of all these tests the Babcock was nearest the standard, the average error of 30 tests being only 0.07 per cent. and it is the simplest test that can be relied upon.

The total solids in milk may be obtained by evaporation and weighing, or estimated from the specific gravity and percentage of fat. The Babcock formula is to divide the two right-hand figures of the specific gravity at 60° F. by four, and add one-fifth of the per per cent. of fat. This gives the total solids not fat. The Richmond scale is a double slide with specific gravity and lactometer readings for different temperatures. It is even more accurate than the Babcock. The amount of proteids can be approximately estimated by deducting 5.3 for cow's milk or 6.7 for human milk (the average amount of sugar and salts) from the total solids not fat.

**Kidney Decapsulation in a Boy of Nine Years.**—The patient, as reported by T. M. ROTCH and H. W. CUSHING (Archives of Pediatrics, Aug. 1903), was uremic, with general edema, ascites, nausea and vomiting. He voided daily 300 to 800 c.c. of smoky, acid urine of sp. gr. 1.010, and containing one-eighth to one-fourth per cent. of albumin and numerous hyaline, granular, blood and epithelial casts. The urea excreted was 5 to 10 grains in twenty-four hours. After the removal of 4,220 c.c. of turbid serum from the abdomen, the kidneys were decapsulated by the usual method, and were found to be enlarged and without cicatricial depressions on their surfaces. The capsules were not adherent. Five hours after operation the boy passed 30 c.c. of urine, and in the first twenty-four hours 62 c.c. containing 0.39 gms. urea and one-seventh per cent. albumin. Improvement was rapid, headache and nausea disappeared, and the edema subsided. On the seventh day the urea was 11.2 gms. in twenty-four hours, the patient passed 1,170 c.c. of urine and was comfortable. The albumin contained one-seventh per cent. From that time the picture changed. The temperature rose to 105° F., pulse fluctuated from 130 to 140, respiration 35, nausea and vomiting recurred, and death followed on the thirteenth day after operation. The urine had diminished to 230 to 350 c.c. a day with 3.6 to 4.6 gms. urea.

## GENITO-URINARY AND SKIN DISEASES.

**Prostatectomy Incision.**—The proper perineal prostatectomy incision is made the subject of discussion by N. SENN (Jour. Am. Med. Assoc., Aug. 15, 1903). Sufficient exposure and complete drainage are the two essentials demanded of an incision, and according to the author neither of these are quite fulfilled by the incisions of Kocher or Zuckerkandl, with which he has had considerable experience. A new incision which obviates the difficulties and disadvantages of the others is proposed by him, representing in outline an inverted Y. The median incision is made in the usual way, laying bare the membranous portion of the urethra. The lateral incisions are carried from the lower angle of the median to a point half-way between the anal margin and the tuberosity of the ischium, cutting through about the same structures as are involved in the lateral operation for stone in the bladder. The wound is deepened by the use of blunt instrument and all bleeding carefully stopped. The rectum is then detached and the lower segment of the prostate exposed. After incising the membranous urethra on a grooved staff which is inserted into the bladder, the finger may be introduced into the prostatic urethra and the gland pulled forward. The capsule is next incised and the author recommends removing one lobe of the gland at a time. Permanent drainage is then secured for the bladder by means of a soft rubber fenestrated drain, the distal end of which is fastened in the lower angle of one of the lateral incisions. The perineal wound is drained with a strip of iodoform gauze which is brought out alongside the rubber drain. The remainder of the wound is sutured and the bladder is kept practically empty by syphonage and may be irrigated daily. The gauze drain is left in about five days and the rubber drain remains until the urine is sufficiently cleared up.

**Treatment of Constitutional Syphilis.**—After discussing the theories held in regard to the action of mercury in syphilis, and the relative merits of administering it continuously, intermittently, or only when the symptoms demand, A. M. FORBES (Montreal Med. Jour., Aug., 1903) lays down the maxim "Begin treatment with mercury as soon as the diagnosis is reasonably clear, and continue until not only the sore but the last vestige of induration has disappeared and some weeks have elapsed without apparent evidences of infection." With a history of illegitimate coitus followed in due course by a sore with rapid induration and then enlargement of the neighboring lymph-glands it is waste of time to wait for secondary manifestations, especially as sometimes the rash is wanting in persons who afterward present grave visceral and other lesions. The internal administration is the most pleasant and convenient but the least effective. With Jonathan Hutchinson, he prefers the mercury with chalk, rather than the bichloride or protiodide, as it permits fair doses of mercury to be given without inducing poisoning or diarrhea, and it is not irritant. He begins with one grain three times a day for an adult and rapidly increases the dose. Mercury by inunction is a more rapid method of treatment, and white precipitate ointment will be found clearer and less irritating than the usually employed "mercurial ointment." The patient rubs a piece the size of a bean to a walnut into the skin of abdomen, axilla, groin or popliteal space, changing the site of application on successive days. With children the salve is placed on the abdomen, covered with a binder, and allowed to work in by the child's movements. The most prompt action and the surest dosage are gained by the hypodermic method. The author keeps powders of corrosive sublimate, each one grain which he dissolves in thirty minims of boiling water at the time of injection. He begins with five minims twice a week injected deeply into the gluteus maximus, and increases the dose till the full thirty minims are given. The process is painful, but abscesses are rare. For tertiary syphilis mercury is useless, but the iodides in heroic doses, though not curative, have a wonderful power to cause the disappearance of the swellings or effusions. In treating syphilis a mouth-wash should always be employed, and if sores in the mouth do not disappear under mercury discontinue the mercury and try a general tonic for a time. In the case of geographical tongue, abstinence from tobacco may prove satisfactory.

## THERAPEUTICS.

**Cure of Angioma Without Operation.**—A modification of the method used by Fiorani in the treatment of angioma has been successfully applied by A. FRATTINI (Gazz. Osped., July 19, 1903) in 30 cases. This consists in painting the tumor with a preparation of corrosive sublimate dram ¾ (gm. 3) and collodion 2 ounces (gm. 50). The author proceeds as follows: A coating of this solution is painted upon the tumor, care being exercised that it does not spread much beyond the margins. After this has dried—the process

being hastened by blowing upon it—a second application is made, and perhaps a third and fourth according to the tumor's size. When the last coat has dried and the tumor is thus covered with a more or less hard crust, it is covered with absorbent cotton held in place by a bandage. The application is repeated in the same manner after an interval of three days; and, in the case of small angiomata, about three days after the second application the crust thus formed falls off and, as a rule, with it the angioma disappears, leaving but a small cicatrix. From three to four applications at intervals of three days are necessary to the cure of the larger angiomata.

**Antistreptococcus Serum.**—In a very readable article F. Meyer (Zeitsch. f. klin. Med., Vol. 50. Nos. 1 and 2) reviews the value of the various antistreptococcic sera and proves that the serum of Aronson is really far superior to all the previous ones and that it holds out alluring promises for the future in the treatment of septic conditions, provided animal experiments can be looked upon as trustworthy criteria. Only those mice which were immunized against the streptococcus with Aronson serum, recovered from fatal doses; the sera of Marmorek and Tavel were absolutely without influence. The same was true when the serum was injected several hours after the infection, though much larger doses were then necessary. The serum of patients recovered from severe scarlet fever had the same immunizing power upon animals. The most efficacious method of administering the serum seems to be intravenously. Occasionally animals died some time after the serum had been given; the spleen here could not be looked upon as the organ where the germs had remained deposited since the same observation was made where this was extirpated. It seems likely that small thrombi enclose and retain the cocci until the action of the serum has passed off, when they rapidly regain their old virulence and destroy life at a time when all danger seems to have passed. It is thus obvious that the treatment must be prolonged for some time after apparent convalescence. It is difficult to get a clear idea how the serum acts, for it does not seem to influence growth in the culture tube. A bacteriolysis never occurs but merely a marked reduction of virulence, for cocci which have been left for some time under the influence of the serum, will no longer bring about hemolysis. The serum will no doubt demonstrate its value in the septic diseases of man to the same degree when physicians no longer wait till the patient is so low that he no longer reacts to anything else.

**Antitoxin in Hay-Fever.**—The further report on Dunbar's antitoxin is not altogether gratifying. Sir Felix Semon (Brit. Med. Jour., July 18, 1903) reports in very great detail his observations on a series of eight cases which he had personally treated. In England, as here, the weather had been so cold that the usual crop of victims had not appeared in time to furnish material for an earlier report. Before the season opened he inquired of Dunbar and Prausnitz whether one should not in chronically recurring cases inject the antibody as a preventive. He was assured that it had already been tried in Hamburg with the result that in some people predisposed to hay-fever subcutaneous injections had been followed by a swelling of the arm into which the injection had been made, lasting for several days and accompanied by erythema and urticaria. It is obvious from this that the antitoxin as at present made must contain toxic or septic properties. Dunbar shares this view, for he says, "It must by no means be concluded that we may not succeed later on in freeing the antitoxin serum from these properties. It could be shown that while the power of the antitoxin increased, the by-effects not only did not rise proportionately but rather diminished. From this I conclude that they have no direct relation to the specific antitoxic substance and that by removing these bodies the efficacy of the serum will not be interfered with. Inasmuch as these unknown substances were of a very powerful and as yet utterly unknown character, it seemed but fair to the public that it should not be made a possible victim to them, as was the case in the early days of cocaine usage. Repeated trials, however, seem now to have shown that such danger does not exist and that it is safe to place the drug in the hands of the patients for self-use." A ready-made preparation of the serum, called "pollatin," has been prepared which seems admirable. The following directions accompany each vial: A small quantity of the serum shall be carried by everyone expecting a hay-fever attack. Immediately on noticing the very first symptoms of irritation in nose or eye, a drop or two should be instilled upon the affected organ. Inasmuch as, by the very nature of the disorder, fresh doses of infection are continually being brought into action, and as a given amount of antitoxin is naturally exhausted very shortly by these factors, it follows that the treatment, except under the most favorable conditions, must be but palliative. In cases where the instillation has been followed by good results it is necessary to determine what part autosuggestion had played. Occasionally the improvement is so very marked that it must in all fairness be excluded. In fine, the serum is not a panacea. It often gives relief in very early stages but rarely cuts short well-established attacks. Whether the use of a serum which, because of the removal of irritating bodies, may be given in greater and more frequent doses than the present one will increase the efficacy of this therapeutic agent remains to be seen.

**The Use of Chloroform in the Preparation of Vaccine.**—While glycerin exerts an action on vaccine whereby the extraneous bacteria are eliminated in the course of a few weeks, Alan B. Green (Proc. of the Royal Soc., July 8, 1903), finds that by the use of a solution of chloroform in distilled water, the extraneous bacteria of vaccine are eliminated in from one to six hours, the specific germ remaining fully potent for vaccination. The solution of chloroform that can be most advantageously employed in the preparation of vaccine is a saturated solution in distilled water, having a strength of 1 in 200. This is the limit of such solubility. The method of preparing the vaccine in this way is a complex one and need not be detailed here. The following are the considerable advantages alleged to be gained by the use of the chloroform process: (1) So speedy an elimination of the extraneous micro-organisms is attained that vaccine, practically free from such organisms, can be distributed for use within a few hours after its collection from the calf. In times of urgent demand for large quantities of vaccine, such as occur during smallpox epidemics, this process must needs prove of great value, since the necessity for wasting some weeks for elimination of extraneous organisms by glycerine will be done away with. (2) In so far as the vaccination value of vaccine depends on the activity of a living organism, deterioration of that value must occur in the course of a longer or a shorter time. The potency of some vaccines, glycerinated or otherwise, becomes greatly impaired within a few weeks of collection, that is, within the time required for glycerin to exert fully its influence in eliminating extraneous organisms. Some of the vaccines may, at the time of their collection, have possessed a high vaccination value. (3) For a similar reason the chloroform process might be of considerable use in hot climates, where the preservation of the potency of vaccine is frequently a matter of considerable difficulty.

# THE MEDICAL NEWS.

*A WEEKLY JOURNAL*

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, SEPTEMBER 5, 1903.

## THE PROPOSED NEW WATER SUPPLY FOR GREATER NEW YORK.

THE awful lesson of Ithaca has not yet been forgotten: hence we cannot overlook the sanitary aspects of the report of the special commission on water supply which is about to be presented for public consideration through Mayor Low. The full text of this report is not yet obtainable. We are informed that it recommends an intake of Hudson River water at or near Poughkeepsie. Three years ago, in the fragrant time of Ramapo, a survey of possible sources of water supply for the growing metropolis was made under Comptroller Coler's auspices; and about the same time a report was published by the Merchants' Association. The availability of Hudson River water was fully discussed at that time; but the demand of the hour was for facts concerning gallons and dollars, and the minor questions of disease and human life were left in the background. It was all but tacitly assumed that the use of polluted river waters was unobjectionable, provided only the scheme of supply included somewhere a method of filtration.

By means of a Poughkeepsie intake, the city of New York could be supplied daily with a quantity of water variously estimated at from 800,000,000 to 1,500,000,000 gallons. Quantity is a desideratum, and the Hudson River at once commands attention; no other possible source offers a greater volume of water. The upper Housatonic would supply a sufficient quantity of water at a greatly reduced cost; but the Hudson River is in New York State and the Housatonic is not. The latter could be controlled only with the consent and cooperation of the legislature of a neighboring State, and even with such cooperation serious legal obstacles to purchase and control would remain. A readjustment of State boundaries is scarcely to be thought of in this instance, though such a readjustment for similar purposes was effected some years ago by Massachusetts and New Hampshire. The Adirondack region is, indeed, geographically available; economically it is excluded, for the cost of an Adirondack system would be double that of the proposed Hudson River works.

The successful filtration of Hudson River water is scientifically possible. Is it politically probable? The adoption of the Poughkeepsie plan should at all events be preceded by a careful consideration of this question. Public works have a moral as well as a material foundation. Wisdom in the plan of supervision is of incalculable value in such enterprises. The use of Hudson River water without adequate purification would reduce New York from its present sanitary rank to a position which public-spirited men would regard as degrading. Now is the time to remember that a public water supply is a public danger.

The Hudson is a foully polluted stream. The wholesale contamination of this body of water begins in the Mohawk Valley. Amsterdam, Schenectady and Cohoes utilize the Mohawk for their water supply and for the disposal of sewage; the typhoid rate of all three cities is relatively high. The typhoid rate in Schenectady is 100 per 100,000; in Cohoes it is 90, in Amsterdam 52. The New York City rate is only 17, and that of Yonkers only 16. The typhoid rate in Albany is still very high, though much reduced since the introduction of filtration. It is scarcely necessary to recapitulate the fifty-odd towns the sewage of which is discharged into the Hudson. It is sufficiently enlightening to point out that from 1890 to 1899, the typhoid death-rate of the maritime counties of New York State was only one-third as great as that of the Hudson Valley.

On the Merrimac River, Lowell and Lawrence needed the terrible epidemic of 1890-91 to enforce the lesson of the danger of polluted river water.

For each ten thousand lives exposed in that time of peril, New York might endanger its million, and it will indeed imperil them if the proposed Hudson River works should fall into the hands of recklessly selfish, incompetent political partisans. Experience teaches that such a calamity is likely to occur at any time in our political affairs.

Under ideal conditions New York would always own its own watershed and would keep it clear and uninhabited. If this is no longer possible, we must at least insist that the city's storage and filtration plants be administered by men of advanced knowledge and of the highest integrity, fully impressed with the weight and dignity of the task of standing guard over the lives of a multitude. A polluted water supply is a merciless public enemy; let us avoid it if we can—outgeneral it we must.

## "WHERE THE BEE SUCKS."

It has often been said, that there is nothing new under the sun, but if this is true, the sun, in these days of modern discoveries, must have swerved enough from its point of fixation to have rendered visible things that were unseen in our childhood's hour. Thus, we remember in the days of our youth a short and rather illicit poem, that stated didactically, that "God made bees, and that bees made honey." Here, however, all reference to their usefulness ceased, and the subject has been generally considered a closed one, until it has been renewed and amplified by one Dr. Perc, of Marburg.

According to this latest apiarial authority, the chief practical aim and object of the busy little bee, is not, as we have been hitherto taught, to improve each shining hour, by gathering honey all the day from every opening flower, but to utilize, what has been christened in the vernacular, his "business end," in the cure of all sorts of rheumatic ailments, but more particularly those of the articular variety.

How the poison of the sting effects a cure, this "Bee Man" does not state. It may be that there is some special virtue in the venom, or it may serve as a general counter-irritant, but from the fact that he claims that "every organism is made immune from bee poison, and also immune from rheumatism," we imagine that it acts—or that Dr. Perc thinks that it acts—empirically, from some peculiar virtue inherent in itself.

What he loses in theory, however, he certainly makes up in practice, and his directions are sufficiently explicit. He permits his patients to be stung at first by a few bees, and then gradually increases the number until the treatment becomes, like the language from the bunk of the friend and partner of *Truthful James*—"both painful and frequent and free." The stings are "inserted," he says, "near the joint of the muscles affected," but here the description of the technic of his operative measures is obscure, as he does not state how the bee is induced to implant his sting at any indicated spot, in any particular region. The insects, it is true, might be lured there, by smearing the parts with honey, but leading a horse to a well does not always end in his drinking, and as Dr. Perc allows seventy stings "at one sitting," his patient's joints must resemble the Psalmist when they compassed him about like bees.

As to the cases that he reports in support of his discovery, one perhaps will be sufficient to indicate his general method of treatment, and will serve to show that even the victims of the most advanced stages of rheumatic disease, need not despair, provided only that they are willing to submit to the by no means homeopathic "course of cure." The case quoted, is that of a woman, age not given, "who suffered excruciating torture from rheumatism." The usual remedies had been tried by other physicians, without success. The salicylates had proved inert and useless, while blisters and counter-irritants had rendered matters worse, and had only served to increase her suffering and discomfort. At this juncture, she came under Dr. Perc's treatment, and, dispairing of alleviation by any other method, placed herself unreservedly under his direction and control. From the time of the first application of the remedy her condition steadily improved, the pain grew gradually less, as the number of stings was increased. The inflammation abated, each joint became more flexible and mobile, one by one, as "some bee had stung it newly," until she became at first convalescent, and then, according to the report, finally cured. This happy state of affairs, however, was not the work of a single day, nor yet of a single bee, while the strength of will of the patient, with her belief in the ultimate success of the treatment, was as marked as that of her less fortunate biblical sister, who had in vain wasted her substance on physicians. For the number of times that she was stung, while en route to recovery, made a grand total of 6,952 stings, which, as Dr. Perc, with unconscious naïveté, remarks, was a sufficient number to insure a complete success.

As to Dr. Perc himself, he has our respect and our esteem. He is blessed with the courage of his convictions, and it is quite evident, from the *London Mail*, that he has resisted all temptations to belong to other nations, and has remained an Englishman. Thus he does not claim that John the Baptist, who dragged out a nomadic and hoboic existence, and who would have been most naturally and constantly stung by bees, in the struggle for his daily honey, was immune from rheumatism on that account. Neither has he as yet laid felonious and uncopyrighted hands on the pertinent advertisement of his American colleagues that his particular remedy "will cure hives and is nice to eat on bread." For these two mercies we can certainly be thankful and if he can succeed in lessening the arthritic pain and anguish of the British public, he should, at least, be not without honor in his own country.

We do not believe, however, that this Theodore Thickthong method will prove a success in the States. The supply of bees could doubtless be increased by raising them in large quantities, so that the price, per thousand, would be decreased.

But the remedy itself is too strenuous and able-bodied to meet with popular approval, and we fear, bad as the evils of rheumatism undoubtedly are, that when it came to the question of to bee, or not to bee, the average thin-skinned American would rather bear the ills he has than fly to those he knows not of.

---

## PRESENT LIMITATIONS OF MEDICAL SCIENCE.

THE beginning of the new century was marked by many eloquent essays upon the brilliant achievements of the hundred years that had just passed and the physician was not the least proud of the scientists to realize how his profession had emerged from a period of superstition into one of enlightenment and progress. Much, very much, no doubt, has been accomplished, but it is timely for us to check our enthusiasm and modestly to acknowledge that much is still terra incognita, awaiting the master mind, not so much for renewed research along the old lines, but for entirely new methods. In pathology and bacteriology especially we seem to have come to a standstill, for, aside from the practical application of the principles of immunity, little of far-reaching importance has been achieved during the last few years. We need but review the long list of important diseases in man and animal, undoubtedly of bacterial origin, but as yet with unknown etiology, to realize with dismay that the enormous amount of laboratory work done all over the civilized world is really without avail and that with the methods at present at our disposal, complicated and time-robbing as they are, we have reached a certain stage and do not seem to advance beyond it. We are to-day almost as ignorant of the germs of scarlet fever, measles, rubella, syphilis, mumps, acute yellow atrophy of the liver, beriberi, noma, Landry's paralysis and a host of other diseases as we were in the days before Koch, and yet hundreds of brilliant minds have spent an untold amount of time and labor in their study.

Truly, Nature does not readily give up her secrets and the time for resting upon our laurels is still far off.

Yet, far from discouraging, these facts will but stimulate to further thought, and already the future holds out many promises. Bacteriologists are becoming conscious of the fact that they must be zoologists as well and that the great group of protozoa may yet be destined to play a more important part in human pathology than at present appears. Much, too, can be expected from more powerful microscopes, for the germs of many diseases are known to pass through the pores of the Berkefeld filters so that a magnification of 2,000 or 3,000 diameters will hardly reveal their presence. And, indeed, a discovery of most promising result is already announced by two Jena professors, H. Siedentopf and R. Zsigmondy (*Annal. d. Physik*, Vol. X, 1903), who seem to have solved the chief difficulty of higher magnification by increasing the illumination of the particles to be examined. Owing to their minuteness, these exert no material influence upon the vibratory period of the light waves and hence appear to the observer as self-illuminating or luminous objects by virtue of their reflected light. Since, however, the reflected light is weaker than the original illuminating beam, it is necessary, in order to secure the advantages of an intensified illumination, to employ the principle of dark-field illumination. This principle is well illustrated by the common phenomenon of the "visible sunbeam" in a darkened room which is penetrated by a ray of light. Dust particles hitherto invisible, can readily be perceived when the eye of the observer is at right angles to the direction of the penetrating ray. If now the illumination is strengthened by employing a more powerful source of light and a condensing lens and the power of the eye is aided by means of a microscopical objective, we have all

the essentials for rendering visible ultramicroscopic particles. By means of their apparatus, the two Jena professors have seemingly accomplished what the great Helmholtz did not conceive as possible. This physicist declared the limit of microscopic perception to be 0.0001 millimeter, while now this limit has been extended to from 0.000004 to 0.000007 millimeter. That such an achievement promises great things in scientific investigation is readily seen.

## ECHOES AND NEWS.

### NEW YORK.

**Dr. Curtis Acting Dean.**—Dr. John G. Curtis, for many years professor of physiology, has been appointed acting dean, to supply the vacancy at the College of Physicians and Surgeons created by the resignation of Dr. James W. McLane.

**Trachoma Hospitals.**—A new hospital for the treatment of trachoma patients from the public schools will be established by the Board of Health some time in October at One Hundred and Eighteenth street and Pleasant avenue. It is the plan soon to establish another trachoma hospital in the Bronx and a third in Brooklyn.

**Tuberculosis Handled by the Board of Health.**—Within a few months victims of consumption will be treated free in a building now being erected by the Health Board on a lot just south of its building in Sixth avenue. The plan is to care for them here until they are in a condition to be sent away to some sanitarium. The success of the open-air treatment at North Brother Island, which was established this summer, had been even greater than was expected. One woman had gained more than twenty pounds, and all the 65 patients were wonderfully improved.

**Governor Odell and State Institutions.**—In a speech recently delivered at Geneseo, N. Y., our worthy Governor, unconsciously confessing the most indefensible part of his administration, said: "Extravagant buildings and useless, high-salaried officials add nothing to the efficiency of treatment in our hospitals or to secure a more efficient administration of our State departments. Such a misuse of public moneys is extravagance deserving of condemnation." His omission to explain the retirement of the local Boards of Managers is noticeable. To the members of these boards the above remarks do not refer, since their offices were filled without salary or even the prospective emolument of political patronage or power. Their notions of the purposes of State charitable institutions were at variance with those of Mr. Odell. He found them with ideas narrowly centered upon the improvement of the unfortunate patients, indisposed to scan the political horizon or give proper respect to his machine.

**Physical Education at Columbia.**—The increasing prominence of school hygiene as a field of instruction is indicated by the announcement that Columbia University has formed a department for the study of physical education in the several gymnasiums connected with the University. The scope of the work can best be shown by the outline of a single course, "Hygiene A." The aim of the course is to give the student instruction in the principles governing the care of the body, to the end that the highest degree of mental and physical efficiency may be obtained. The body will be studied as an organism and as a machine. The study will not be from the standpoint of anatomy or physiology; only a broad outline of the structure and functions of the body will be given, and that only as a basis for the application of hygiene. The course will include a full discussion of the following topics: Muscular activity, its uses, its aims, its methods, and the relative value of the various forms of exercise, general and special; feeding, nutritive value of various foods, relative value of various beverages, the effects of alcohol on the organism, dietaries, and the abuse of stimulants and narcotics; sleep and rest, the expenditure and recuperation of energy, the general regulation of nervous activity; bathing, fresh and salt water bathing, sponge, tub, shower, douche, and plunge baths, thermal baths, the value and danger of the morning cold bath; clothing, heat radiation, conservation of energy in the body, uses of clothing for protection and adornment; sanitary conditions of the home, the site, construction, plumbing, heating, and ventilation; the adaptation of man to the changed conditions of his environment in the cities during the last one hundred years, the change from outdoor to indoor life, the greatly increased demand for nervous energy, with a corresponding decreased demand for muscular energy; the influence of heredity, extent to which mental, moral, and physical characteristics are inherited; the influence of climate on the organism, acclimation, organs most affected by different climates, tropical, cold, temperate, dry, moist climates, fertile and sterile soils, sea air and mountain air, healthful and unhealthful climates; protective measures against infectious diseases, the germ theory of disease, communicable and contagious diseases, immunity, serums, vaccination, boards of health, duties of citizens concerning quarantine regulations, water and gas supply, inspection of milk and foods. A course by Professor Wood will treat of the physical organization of the child; laws of heredity, growth, and development; home conditions necessary to the child's health; school environment; functions of the school physician; prevention of disease and deformity by hygienic surroundings, healthful postures, and activities; adaptation of gymnastic exercises to the different grades; and the regulation of athletics. The medical director, in addition, will hold office hours daily, acting as a consultant and advisor to any student seeking his services. Each student will be entitled to a physical examination, on the basis of which the general hygienic regimen and physical exercise best suited to his peculiar needs will be prescribed.

### PHILADELPHIA.

**Suicide Increasing in Philadelphia.**—Statistics recently published show that for the years 1892 to 1901, inclusive, Philadelphia was twenty-sixth on the list of 50 cities as regards the number of suicides. For the year 1902 Philadelphia is twenty-fourth in the list, the increase being from 11 to 13 per 100,000. The figures for 1002, however, do not agree with those of the coroner who in his annual report, states that inquests were held in the cases of 203 suicides, which would be a ratio of 15 per 100,000.

**Further Action Against the Alba Dentists.**—Attorney-General Carson has directed a writ against the Alba Dental Company of this city requiring that corporation to show cause why it should be allowed to practise dentistry in Pennsylvania. This proceeding follows the recent conviction and sentence of the president and manager for having employed stu-

dents who were not licensed dentists. It is alleged that the corporation is not exercising any of the objects authorized by its charter and that the president, although he owns 98 of each 100 shares of stock, is neither a dentist nor a physician. The company has 11 offices in this city.

**New Hospital in Coatesville Dedicated.**—The new public hospital which has just been completed in Coatesville was dedicated August 29. The building is erected on a high hill in the southwestern part of the borough and is 100 by 80 feet in size. It contains three large wards and ten private rooms. The total cost was over $30,000, a considerable portion of which was donated by Mr. and Mrs. Charles L. Huston, who for the past four years have maintained the Huston Memorial Hospital at an annual expense of $6,000. The rapid growth of the town rendered this hospital inefficient. Both regular and homeopathic physicians will be on the staff of the new hospital.

**Library of the College of Physicians.**—Dr. F. P. Henry, honorary librarian of the College of Physicians, of Philadelphia, has written for the *Ledger* an interesting historical sketch of the library of that institution. The library, which is the second greatest medical library in the world, was begun in December, 1788, when Dr. John Morgan, the founder of the Medical Department of the University of Pennsylvania, presented to the college 24 volumes. The number of volumes is now 67,243, many of them being exceedingly old, first editions, and practically invaluable. Dr. Henry states that in one particular, at least, this library is first of its kind. This point is the extreme liberality of its management. It is not only open to every one, whether physician or layman, for consultation, but the Fellows of the College have the privilege of taking out books for two weeks, and extending the time, if the book has not in the meantime been asked for, to two weeks more. There is but one restriction to non-members, namely, that they must present a card or note of introduction to the librarian from one of the Fellows of the College. This rule has proved satisfactory to all parties concerned. With the new building, which the Carnegie Fund of $50,000 has made possible, the library of the College of Physicians will begin a new era of usefulness.

## CHICAGO.

**Typhoid Fever.**—During the last week the increasing demand for laboratory examination of suspected cases of typhoid fever has been noticeable, although the hospital reports and the typhoid mortality do not show any such increase. On the contrary, the number of cases in hospital remains about stationary, while there were but 17 deaths from the disease reported as against 53 for the corresponding week last year.

**Smallpox.**—Of the twelve cases of smallpox removed to the Isolation Hospital during the week, six contracted the disease from an unreported convalescent found in the rear of a saloon. Ten of the 12 cases had never been vaccinated; 2 had imperfect vaccination marks more than twenty-five years old. The type of the disease this year is much more serious than last year.

**Changes in the Laboratory Force.**—The process of reorganization in the Chicago Health Department began last week with the temporary appointment of Dr. J. F. Biehn as assistant bacteriologist, succeeding Dr. L. A. Kierulff, resigned, and the temporary detail of Dr. George E. Masslich as city chemist, in the absence of City Chemist D. B. Bisbee. While both of these appointments affect only the city laboratory they are regarded as the forerunners of a sweeping change.

**Chicago the Virile.**—Of all the larger cities of the country Chicago has the largest proportion of males in its total population. During the last twenty years Chicago has averaged 5.3 per cent. more males than females, while New York has averaged 2.8 per cent. more females than males, Philadelphia 5.7 per cent. and Boston 7 per cent. more females than males. Not only this, but Chicago's male death-rate is the lowest of the four cities—Chicago, 20.5 per thousand; Philadelphia, 22.9; Boston, 23.5; New York, 27.1, being the averages of the three Federal Census years 1880, 1890, 1900.

**Willard Hospital in Chicago.**—Directors of the Frances E. Willard National Temperance Hospital have decided to erect a $75,000 hospital in Chicago. The building will be the culmination of nineteen years' work on the part of the Directors, all women, and will crown the efforts to treat diseases without the use of alcohol. The building will be five stories high, and one of the wards will be dedicated to the use of the Loyal Temperance Legion, a society of children. The staff of the hospital includes prominent members of three schools of medicine.

## GENERAL.

**More Plague in Peru.**—Three new cases of bubonic plague are reported in Pacasmayo, one in Molendo and two in Lima.

**Fasting as Cure for Dyspepsia.**—Ex-Judge Ellis, one of the best-known lawyers in western Kansas, died last week at his home in Platt. He had followed a theory of fasting to cure dyspepsia and had gone thirty-seven days without food.

**Molasses and Murder.**—Five natives were murdered in August on Diomedos Islands, in Behring Sea, in consequence of a frightful orgy among Eskimo, following the sale to natives of molasses by whalers. The molasses was utilized for the manufacture of a fiery liquor called "hatch." Under the influence of this intoxicant usually calm and peaceful natives become like maniacs.

**Dr. White Appointed.**—William A. White, first assistant physician at the Binghamton State Hospital, has received from the Secretary of the Interior the appointment as superintendent of the Government Hospital for the Insane, at Washington, vice Dr. Alonzo B. Richardson, who died on June 27 last. Dr. White, who is thirty-three years old, is recognized as one of the foremost alienists in the United States. He will leave within a week to take up his new duties.

**Army Sanitarium Inspection.**—Surgeon-General O'Reilly of the United States Army, and W. B. Jansen, of the Atchison, Topeka and Sante Fé Railway, have returned from a tour of inspection of the army sanitarium at Fort Bayard, N. M. Montezuma Hotel, at Las Vegas Hot Springs, owned by the railroad company, had been closed for lack of patronage, and may be turned over to the United States Government for sanitarium purposes. It is understood that the Surgeon-General favors the plan.

**Attacks Census Figures.**—F. L. Hoffman, of Newark, University Lecturer on Actuarial Subjects, at the Fourth International Congress of Actuaries, which met in New York during the current week, paid his respects to official statisticians in the United States, especially to the Census Bureau. "When we are told," he said, "by a Secretary of War that the mortality of the army in Cuba was not greater than that of the City of Washington we do not need large

actuarial knowledge to smile at the statement and dismiss it as without statistical value—a misleading item disseminated to an ignorant public for political purposes." The United States Census Bureau, Mr. Hoffman declared, though not now "in such atrocious shape" as it had been before it became a permanent department, was "very far from being such as to give its statistics value as contributions to science." The bureau needed, said Mr. Hoffman, the services and advice of expert actuaries.

**A Great Problem Settled.**—The problem of epilepsy is admittedly one of great antiquity. We are tolerably sure that it has deeply puzzled physicians in all countries since the days of Hippocrates. The individual, therefore, who has the power of suddenly knocking the lid off the mystery box and showing us at a glance "epilepsy shorn of all mystery" is entitled to our best obeisances, to say nothing of our debt of undying gratitude. It appears that the honor of such a discovery belongs to a young physician who confesses in a recent article on "What Is Epilepsy?" that "there is nothing mysterious or even enigmatical about the disease." He goes on to prove to his own satisfaction that epilepsy is caused by vasomotor spasm that results finally in auto-asphyxia. Auto-intoxication in turn causes the vasomotor spasm. One wonders at the writer's seeming inconsistencies, for after asserting that "there is nothing mysterious or enigmatical" about epilepsy, he concludes as follows: "And if we could but lift the curtain which hangs behind the vasomotor spasm, I believe that the long-sought cause of epilepsy would stand revealed." Is the cause of scientific medicine ever advanced by flashes of inconsistencies as great as these?

**Tuberculosis Aid and Education Association.**—A new association for the alleviation of tuberculosis and the education of the community hopes soon to commence active work in Cambridge, Mass. Its constitution says: "This Association shall be called the Tuberculosis Aid and Education Association," the object being, "To cure at home, if possible, persons suffering with tuberculosis; to relieve with food, as far as possible all needy tuberculous persons; to educate the entire community in the care and prevention of this disease; to promote the establishment of hospitals for hopeless cases." A deep interest is being awakened in the community, and representative men and women are to be found on the Board of Managers. The Advisory Expert is Dr. Edward O. Otis, of Boston, an eminent lung specialist, at one time President of the American Climatological Association. Dr. J. L. Hildreth, a prominent physician, is chairman of the Advisory Board, consisting of twelve physicians who will advise the Board of Managers on medical matters. A trained nurse will care for such cases of the poor as need her attention, free of expense, giving instructions as to the disposition of sputum and the formation of healthful habits. Various committees will have charge of the distribution of food, of lectures, of sanitation, etc. The movement is intended to be largely educational and for this reason there will be on file, open to the public, reports from other organizations working along similar lines, reprints from papers read by physicians before medical and other societies, and pamphlets descriptive of public and private sanatoria. The committee will be grateful to physicians and others, who will donate any of the above. If possible, they would like three copies, one for the library, one for a special room devoted to advisory conferences, and one for private consultation by the Board of Managers. While it is not the intention of the association to become an advertising medium, the committee in charge of outlining the work, feel so deeply the value of sanatoria treatment in the early stages of the disease, that they wish to put themselves in touch with such institutions. They feel that such a collection of information will be invaluable to physicians in advising patients to try a climate peculiarly fitted to each case. With the booklet from sanatoria it would be well to send a brief description of the shortest route of travel between Boston, Mass., and the sanatoria, hotel or boarding house at which tuberculous persons are received, and the price for board or treatment.

**Ithaca and Typhoid.**—Dr. G. A. Soper, special consulting expert of the State Health Department, in connection with the Ithaca typhoid epidemic, has resigned that position. Dr. Soper says that typhoid would be stamped out at Ithaca if the local authorities would follow his instructions, but they have not even appointed a Health Board to succeed the officers who recently resigned.

**The Milk Problem.**—The Agricultural Department at Washington has made a contribution to the general discussion on the quality of milk supplied to cities, a bulletin, a large part of which is devoted to the question of transportation. The bulletin says the agitation of the question of impure milk has resulted in improved practices on the part of persons handling this article of food, but there is still much room for improvement. For instance, attention is called to the fact that the ideal vessel for the conveyance of milk remains to be discovered. There are many cities and towns which have no legal regulations whatever concerning milk. Many suggestions are made for the improvement of the milk supply, among which are the following: (1) The registration of all dairies; (2) official endorsement of properly conducted dairies; (3) inspection of all herds, barns, and dairy buildings once a month; (4) better lighting, ventilation, drainage, and cleanliness of cow stables; (5) whitewashing the interior of stables; (6) eradication of tuberculosis from dairy herds; (7) branding of condemned cows; (8) pasturage for city cows; (9) aeration of milk in pure air; (10) prompt cooling of milk and holding it at a low temperature until final delivery; (11) shipment of milk from farms promptly after milking; (12) delivery of milk and cream in sealed packages. It is noteworthy that these recommendations correspond very closely with those formulated by the Milk Commission of the Medical Society of the County of New York.

**Autumnal Typhoid and the Oyster.**—A recent issue of the *British Medical Journal* contains an official report by Dr. H. T. Bulstrode on the outbreaks of typhoid fever attributed to raw oysters, which followed two of the municipal banquets of last year. On November 10 last, Mayoral banquets were given at Winchester and Southampton, towns a considerable distance apart. Each banquet was followed by an outbreak of illness among the guests, as nearly identical in diagnosis and clinical history as possible. In both cases the percentage of guests attacked was about the same, and included only those who had partaken of raw oysters. None of those who did not eat oysters became sick. A close inquiry established the fact that the only dish of which all the guests attacked partook was the oyster course. The oysters served at both banquets came from the same source, Emsworth, on the same day and, presumably, from the same bed. At Winchester 62 out of 134 guests were attacked, of whom 10

developed typical cases of typhoid fever, the remainder escaping with what might be called abortive attacks. At Southampton 55 out of 132 guests were attacked, and 11 developed typhoid fever. The marked increase in typhoid fever in most cities during September, largely among those who have returned from the country, and are supposed to have brought the infection with them, suggests the inquiry whether indulgence in sea food may not account for this rise in the enteric curve every autumn.

**Obituary.**—Dr. George B. Russell, one of the oldest and best-known physicians of Michigan, died at his home in Detroit August 31, aged eighty-seven years. He was born in Russellville, Chester County, Penn., and did fearless work during the cholera epidemic at Philadelphia in 1836 and in the outbreaks which raged in that city in 1844 and 1845.

Dr. Alexander Montague Atherton, twenty-eight years old, died at Liberty, N. Y., August 28. Dr. Atherton was born in Honolulu, H. I. He prepared for college at Pimaho Academy, Honolulu, and afterward was graduated from Wesleyan University at Middletown, Conn. Later he studied medicine and obtained his degree from Johns Hopkins University in 1901. He won a service in the City Hospital, Blackwell's Island, New York, where, during his interneship, his health began to fail.

Dr. William C. Barrett, dean of the dental department of the University of Buffalo, died in Nauheim, Germany, on Sept. 2. Dr. Barrett went to Nauheim on account of heart trouble, with which he had been afflicted for about a year and which caused his death. Dr. Barrett was one of the best known dentists of this State. He was a member of the American Medical Association, a former president of the Dental Society of the State of New York and a member of the American Microscopical Society.

## CORRESPONDENCE.

### OUR LONDON LETTER.

(From Our Own Special Correspondent.)

LONDON, August 22.

DEATHS OF EMINENT PHYSICIANS—LORD SALISBURY DYING—MEDICAL LEGISLATION.

THE medical profession of this country has within the last week or two lost two of its most distinguished members. Dr. William Smoult Playfair, who died on August 13, was for many years the leading obstetrician in London. He was a brother of Lord Playfair, who was for some time professor of chemistry in the University of Edinburgh and afterward played a considerable part in Parliament. W. S. Playfair, was was sixty-seven years of age, after taking his degree at Edinburgh in 1856, went to India, where he served during the Mutiny. The climate, however, did not suit him, and he returned to Europe. He determined to try his fortune in London, where he settled in 1863. He used to say that he came here, an utterly unknown man, all his worldly goods being represented by a capital of five thousand dollars. He had the good luck to be appointed professor of midwifery in King's College and obstetric physician to the hospital attached to that institution. At that time the influence of that consummate surgical artist, Sir William Ferguson, was paramount at King's and Playfair doubtless owed his appointment largely to his "brither Scot." He made good use of the opportunities of learning his work afforded him by the hospital and became, in the elegant phrase applied by Ferguson to his predecessor, Priestley, a most successful "fumbler of aristocratic vaginas." Among his patients were several members of the Royal Family, including Her Imperial Highness the Russian Duchess of Edinburgh. Some years ago, however, Playfair, for some reason, lost the greater part of his royal connection, his place at the bedside of parturient princesses being taken by Sir John Williams. It was said that Playfair's fees were considered too high, and this may possibly have been the case, for royal personages are apt to look upon the mere honor of ministering to their august persons as in itself a sufficient reward. Whatever may have been the cause, Playfair certainly lost the favor of the Court. Hence he remained plain "Dr." Playfair, having the mortification of seeing titles and distinctions showered on the man who was preferred to him. There can be no doubt that Playfair was hardly dealt with. Apart from his services to royalty, his professional eminence fully entitled him to one of the titular decorations by which merit is recognized in this country. Whatever chance he might have had of such distinction was, however, destroyed by the famous trial in which he had the misfortune to be the most prominent figure a few years ago. As the case is a *cause célèbre* in the annals of British jurisprudence, and as the result makes it of momentous importance to all members of the medical profession, it may not be uninteresting to recall its principal features.

An Australian lady who had married a brother of Playfair's wife consulted him about certain symptoms. He examined her under an anesthetic and came to the conclusion, as she was not living with her husband at the time, that she had misconducted herself. He communicated his suspicion to his wife, who in turn told it to a relative who was making the lady concerned a considerable allowance. This was discontinued, and the lady and her husband brought an action against Playfair for slander. Her cause was pleaded by Mr. Lawson Walton with such ability that the jury awarded the unparalleled damages of $60,000. By a settlement arrived at later between the parties the amount was diminished to $46,000, but the damages remained a "record" in our courts, till the other day, when in a divorce case the same advocate got for the wounded honor of an outraged husband the substantial compensation of $1,250,000. Dealing with the question of professional secrecy, the judge, Sir Henry Hawkins, now Lord Brampton, said that the medical profession had no power to legislate on the matter. They might make their own rules—and he daresay they did so to the best of their ability—for their guidance as professional men, but they could not impose upon the public their self-made laws, as being binding upon them. The medical gentlemen called on behalf of Dr. Playfair said that they were only rules by which they regulated their own conduct. They mentioned two exceptions. In the case of a witness being called into the witness box in a court of justice, and asked to divulge a professional secret, they held that under those circumstances they were bound to give utterance to it. The judge declined to discuss the point, because he had a little doubt whether the rule could be stated so generally as that. Having regard to a variety of circumstances, there might be some matters which the judge might think unreasonable to be divulged by a professional man, and therefore he might refuse to permit it, and allow the witness to refuse to answer. He did not think, therefore, that because of the rule made by medical gentlemen they were bound in all cases where they were asked a question by counsel in court as to professional secrets, to answer. In his mind, they were not, in all cases, bound to answer. Each case must be considered by its own particular circumstances and by the ruling of the judge who happened to preside on the

occasion. It must be taken for granted that the judge would decide according to law. There was always a rule to set a judge right if he went wrong; on the occasion, however, on which he was ruling, his ruling would have to be taken as law. It was also said by the medical witnesses that if in the course of professional practice they came across a case which indicated either that a crime had been committed or was about to be committed, they were bound to divulge it. To whom? To the Public Prosecutor! If a poor, wretched woman committed an offence for the purpose of getting rid of that with which she was pregnant, and of saving her character, her reputation, and, it might be, her very means of livelihood, and if a doctor was called in to assist her—not in procuring abortion, for that in itself was a crime—but called in for the purpose of attending her and giving her medical advice—how she might be cured so as to go forth about her business, the learned judge doubts very much whether he would be justified in saying to the Public Prosecutor: "I have been attending a poor, young woman who has been trying to procure abortion with the assistance of her sister. She is now pretty well, and is getting better, and in the course of a few days she will be out again, but I think I ought to put you on to the woman." To his mind a thing like that would be a monstrous cruelty. Therefore, when it was said that there was a general rule existing in the medical profession, that whensoever they saw, in the course of their medical attendance, that a crime had been committed, or was about to be committed, they were in all cases to go off to the Public Prosecutor. The judge felt bound to say that it was not a rule which met with his approbation, and he hoped it would not meet with the approbation of anybody else. There might be cases when it was the obvious duty of a medical man to speak out, as, for instance, in a case of murder. A man might come with a wound which it might be supposed had been inflicted upon him in the course of a deadly scuffle. It would be a monstrous thing if the medical man might screen him and try to hide the wound, which might be the means of connecting the man with a serious crime. That was a different thing altogether. All the medical witnesses had admitted that professional secrecy was inviolable with certain exceptions. He (the learned judge) had mentioned the one of the witness in the court of justice, and also the other where a crime was brought to the attention of the medical man, and now came to a third. Communications between a doctor and his wife or children were said to be privileged where it was necessary to reveal them in order that the wife or children might be protected. He thought that that required a great deal of limitation, because cases might be imagined where the wife might be living under circumstances in which she did not want any such protection at all, and giving to her a secret belonging to a patient would be only a wanton violation of the rule. It was, however, a very delicate question, and would have to be argued some day. It will be seen that the learned judge left the question of professional secrecy precisely where it was before—that is to say, in a state of confusion which places the medical witness absolutely at the mercy of the judge. Dr. Playfair had the sympathy of the profession, and this was manifest in a striking manner at a banquet given in his honor on the occasion of his retirement from his chair at King's College. At that banquet, which was presided over by Lord Lister, many leading members of the profession were present.

Lord Lister referred to the trial, which he spoke of as a travesty of justice that did not in the slightest degree diminish the esteem in which Dr. Playfair had previously been held. All those present, whether former students, former colleagues, or others, rejoiced in this opportunity of doing honor to Dr. Playfair, and united in a cordial wish that his retirement from the hospital and professional duty might be followed by many years of health, prosperity and happiness. Dr. Playfair, in answering the toast, said he could not refrain from making some remarks about the trial, and he might mention that Mr. Gladstone, to whom he was practically unknown, had done him the signal honor of writing to him a letter not marked private, so that he was justified in quoting it. In this letter Mr. Gladstone said: "Having most carefully studied all the evidence in this trial, I can come to no other conclusion than that you have done neither more nor less than your duty."

Dr. Playfair had prostatectomy performed on him last year by P. J. Freyer, after four years of catheter life, borne with great fortitude. In the spring he had a stroke of apoplexy at Florence and in the summer he came home to St. Andrew's to die.

Dr. George William Balfour, who passed away in his eighty-first year on August 9, was for many years one of the leading clinical teachers at Edinburgh. His advice was much sought after, especially in cases of heart disease, on which he was a leading authority. His books on diseases of the heart, and especially on the senile heart, rank among our classics of medicine. He began professional life as a veterinarian, but soon betook himself to medicine. He was a man of the type of character which the Scots themselves call "dour," and was more respected than loved by his professional brethren. He had none of the graces of manner which make the fashionable doctor, but he was certainly a great physician. He was an uncle of Robert Louis Stevenson.

As I write, Lord Salisbury, who was for so many years the ruler of this country, is dying of cardiac dropsy. He has suffered for a long time from Bright's disease, and his health, never strong, was undermined by hard work. He is attended by Sir Richard Douglas Powell and a young doctor named Walker, who half a dozen years ago was an obscure country practitioner, apparently with no prospect of ever being anything else. He had the good fortune to be called in an emergency to the late Lady Salisbury in her last illness. She took a great fancy to him, and her husband took him up and launched him among the aristocracy. Now he is the trusted adviser of half the peerage, a fact which of itself is sufficient to gain for him the confidence of the British public.

Parliament has been prorogued. The session just ended has been practically barren of medical legislation. A bill to amend the Medical Acts was among the "innocents" included in the slaughter which occurs every year at this time. Practically all that has been done has been to continue for another year the existing vaccination act, to which we owe the "conscientious objector." The government was just as glad to temporize on the matter of so contentious a measure. But the question will have to be faced next year, and the opponents of vaccination are preparing for the struggle.

---

**Lesions of Gout.**—The necrotic areas seen in tissues where urates are deposited are not considered by K. A. Krause (Zeitsch. f. klin. Med., Vol. 50, Nos. 1 and 2) to be really necrotic in the pathological sense of the word, since all the structure of the cells is lost completely. He believes they are merely embedding substance together with the frame-work of the crystals which are invariably found here. The crystals are not, however, limited to such location; they also extend between cells which in every way appear normal. Though the relation between the crystals and the so-called necroses is not cleared by this article it seems probable that death of tissue does not precede the deposition.

ANATOMY AND THERAPY OF EXTRA-UTERINE PREGNANCY—TUBAL AND INTRAMURAL PREGNANCIES—VAGINAL OPERATION AND ECTOPIC GESTATION WITHOUT SHOCK—THE MECHANISM OF BIRTH—THE BIOCHEMICAL EXAMINATION OF THE BLOOD—ANALYSIS OF THE BLOOD AND URINE—PHYSIOLOGY OF METABOLISM BETWEEN FETUS AND MOTHER—ECTOPIC PREGNANCY—PERMANENT RESULTS OF OPERATIONS—RULES FOR OPERATING—CAUSE AND PREVENTION OF PUERPERAL FEVER—UTERINE CANCER—PSEUDOPAPILLARY OVARIAL CYSTS—SCOPOLAMIN HYDROBROMATE WITH MORPHINE TO PRODUCE ANESTHESIA.

THE chief topic of discussion of the German Society for Gynecology, which met at Würzburg June 2 to 6 was the Anatomy and Therapy of Extra-uterine Pregnancy. The congress was opened by a paper by J. VEITH and WERTH upon the still obscure, early changes which take place in the tube when a fertilized ovum becomes definitely lodged there. The reflexa is then formed in part by the folds of the tube, but besides this there is another true reflexa of varying development. The hole in the epithelial layer through which the ovum slips, will again close and the tissue which bridges over the gap constitutes this reflexa. As the ovum increases in size, its peripheral portions will exert a destructive action upon the maternal tissue so that a strip of coagulation necrosis is regularly found where fetal and maternal cells meet. This is not due alone to the hemorrhages which are so common here. Views were also exchanged upon the position the developing fetus acquires with reference to the walls of the tubes and it was generally conceded that it was imbedded within the muscular layer. Tubal abortion is merely a result of development under unsuitable conditions since hemorrhages will readily occur by destruction of the weak layer between the ovum and the lumen of the tube and by the arrosion of vessels. In the majority of cases this will bring about an early death and extrusion of the egg. It is entirely wrong to look upon every ectopic pregnancy as if it were a malignant neoplasm; this view should only influence therapy in case the fetus is alive and steadily developing.

H. W. FREUND refers to five cases operated by him which closely simulated tubal pregnancy. Twice the condition proved to be pure hematocele, twice tuberculosis and once a neoplasm. Hematocele pure and simple is not so rare as some would believe, and is due to mechanical hyperemia or general venous stasis. One is not justified in pronouncing a case tubal pregnancy, if chorionic villi cannot be found in serial sections. The assumption that the egg may have fallen from the tube is untenable in view of the fact that it is firmly imbedded. Analogous conditions are the hemorrhages into the uterus and its mucous membrane in apoplexia uteri, the ovarian hematomata in local and general congestion and the hematosalpinx in congenital and acquired tubal occlusion.

The lodging of an ovum in an accessory tubal diverticulum is considered by FÜTH of great importance. Fetal and maternal epithelial cells will come in contact and the former will acquire the upper hand. The tubal tissues will not grow in proportion to those of the ovum so that part of the surface of the latter will soon project into the tubal lumen. Everywhere one misses the power of adaption on part of the mucous membrane.

Five interesting cases are reported by HEINSIUS, viz., one of intramural pregnancy, the ovum being situated in the muscularis of the uterus; one of ectopic gestation with ovum between a main and an accessory tube at the fimbriated end and three cases of tubal abortion. Of these, one was complete so that the blood pressed out the egg at the fimbriated end, in the second the egg remained as foreign body within the tube, since the marked convolutions prevented an extrusion and in the third there was secondary rupture with tearing off of a tubal fold. Interference with the growth of the ovum is due to the destructive growth of the Langhans cells; they continue to proliferate for some time even after the death of the ovum. Reaction in the maternal tissue manifests itself in the form of edema and hyperemia in the immediate neighborhood of the egg. The variations in the pathological process depend upon (1) the individuality of fetus and mother. Generally the fetal cells show a greater power of reproduction. (2) The length of duration of the pregnancy. As the fetus develops, the fetal cells will divide less actively, the maternal more so. (3) The time that has elapsed since pregnancy has been interrupted. Concerning therapy, the following may be said: The living ovum is a constant menace to the mother, while, if dead, there is always the possibility of renewed hemorrhage from the site of insertion. Hence early, conservative operation is the most safe procedure.

The Therapy of Extra-uterine Pregnancy was the title of a paper read by SARWEY. He states that an operative procedure is always indicated: (1) In the second half of pregnancy, whether the ovum is alive or dead; (2) also in the early months if the ovum lives; (3) with recent rupture and signs of profuse, internal hemorrhage. An expectative and symptomatic treatment is in place with dead ovum and tubal abortion with or without hematocele except with (*a*) decomposition of the hematocele; (*b*) symptoms of pressure and severe attacks of pain; (*c*) accompanying severe disease of the generative organs, which requires operation. When the conservative treatment is carried out, preparation for immediate operation must be made. This must be resorted to (1) with steadily increasing hematocele; (2) where absorption does not follow and the patient becomes weary of her long illness. The abdominal method is to be preferred since better access is gained and the hemorrhage is more readily controlled. Colpotomy is to be restricted to cases of uncomplicated tubal mole without hematocele and to hematoceles which have suppurated.

STRASSMANN reports favorably upon vaginal operation in ectopic gestation if rapidly performed, without shock and without subsequent dangers of a hernia. He does it especially with unruptured sac, with free hemorrhage and with less recent tumors with exacerbations. Drainage is not necessary except where a large cavity is encountered.

The paper of FEHLING contains some valuable remarks upon the mechanism of birth. Where the forceps are applied with the head low down in the pelvis a number of accessory rotations occur which can be used to assist birth by applying 2 or 3 fingers of one hand to the small fontanelle or sagittal suture. Rotation of the anterior shoulder may be resorted to to assist rotation of the head. Excessive rotation may be brought about by a wrong position of the patient, especially in multiparæ.

The biochemical examination of the blood of pregnant women is discussed by OPITZ. He was not able to detect substances specific for placental tissue by means of the precipitin reaction, in the blood of pregnant women. An antitoxic serum against human syncytial toxins was manufactured and injected into eclamptics with due care, but conclusions cannot yet be drawn from the results.

LIEPMANN speaks upon the biological detection of placental substance in the blood and states that he has succeeded in isolating a serum specific for the placenta,

Retroplacentar and fetal blood gives the characteristic reaction and porticulary rapid precipitation occurs with the serum of patients suffering from nephritis gravidarum.

A careful analysis of the blood and urine in eclampsia, forms Zangemeister's contribution. Red and white cells are increased, the molecular concentration and the nitrogen in the serum are increased and the alkalescence of the blood diminished. Proteids and chlorides occur in normal proportions. There seem to be marked variations in comparison to normal blood. Since these changes are occasionally absent they cannot be looked upon as the cause of eclampsia, but must be interpreted as secondary to retention of urine or circulatory disturbance. The amount of water in the urine suffers a reduction which is most marked during the attacks but again is not the direct cause of the convulsions, since these often cease before the disappearance of oliguria. The same may be said about the retention of salt. The cerebral symptoms point to a spasm of the cerebral vessels. Uremia is not the direct cause of eclampsia, but the latter is frequently complicated by a secondary uremia.

Mandl then follows with a paper upon the Physiology of Metabolism Between Fetus and Mother. Various drugs injected into the mother, readily passed over into the fetus, no matter whether the fetus was still in the uterus, or only in its membranes or simply connected with the mother by means of the umbilicus. Thus atropine caused mydriasis and pilocarpine profuse perspiration. Adrenalin alone did not pass into the fetal circulation.

The second day of the congress was devoted to the demonstration of a number of interesting specimens of Ectopic Pregnancy and to the discussion of operations for prolapse.

A. Martin does not consider position of the uterus and trauma at birth of such great importance in the causation of prolapse. In virgins, tuberculosis and masturbation are of prime importance; in married women the loss of resistance on part of the connective tissue. Trauma, inflammation and tumors are only the exciting causes. Hence constitutional treatment and care during the puerperium, climacterium and after infectious diseases are of the greatest importance. Pessaries do not constitute prophylactic measures, and it is more rational to resort to early operation. Later the interference is rendered more difficult and extensive. The best plastic method and the best means of fixation are not yet decided upon. Extirpation of uterus and vagina is only rarely indicated though the results are good. To pass judgment upon the value of the various operations, surgeons must carefully individualize and all patients should be reexamined after a certain time.

Küstner lays stress upon the correction of malposition of the uterus to avoid bad results. A recurrence generally occurs in the first year after operation. He does not criticise pessaries so severely as Martin and believes they are certainly in place where patients can take care of themselves.

Halban and Tändler have found that a marked difference exists between the anatomy of vaginal prolapse with elongation and true uterine prolapse; in the former the relations are almost normal, while in the latter there is a maximum descension of the entire pelvic floor. Hypertrophic elongation does not always consist of a lengthening of the cervix, but in the majority of cases of an elongation of the lower uterine segment.

Ziegenspeck ascribes prolapse to a difference between abdominal and atmospheric pressure. Deficient involution during the puerperium and tearing off of the vagina from the levator most frequently disturb the normal relation. Hypertrophy of the prolapsed portion is generally only apparent, and caused by edema. The uterus could not be artificially prolapsed in cadavers, probably on account of long previous illness which permits the organ to slip back. In recent cases massage is excellent and a narrowing of the soft parts of the pelvic outlet will cure every case.

Schaeffer believes that the frequent combination of prolapse with vasomotor and nervous disturbances points to a primary as well as secondary origin of the latter. The very interesting blood-examinations are too extensive to be published in full.

Koblank, of Berlin, then delivered a lecture upon the permanent results of operations. A definite opinion is only to be passed after four years and the character of a delivery during this time must be taken into consideration. Of the cases observed, 44 per cent. were cured, 34 per cent. were partially cured and the remainder suffered from a recurrence. Part of the failures depended upon neglect of the elongated cervix. Posterior displacement of the uterus plays no part in the etiology of prolapse. Both retroflexion and prolapse are a result of relaxation of the connective and muscular tissues of the pelvis and both do not in any way influence each other. Prolapse in advanced age has the same causes, the disappearance of adipose tissue plays only a minor rôle.

Schauta divides the operative procedures into three groups, viz.: (1) Plastic operations on vagina, perineum and cervix; (2) anterior displacement of the uterus; (3) in advanced cases, excessive antefixation, by anchoring the uterus at the vagina. Of late, Schauta amputates the cervix and shortens the sacro-uterine ligaments, then fixes the uterus to the vesicovaginal septum and finally does a colpoperineorrhaphy. The only disadvantage is that pregnancy will be difficult, hence the ovaries must be removed before the climacteric. Among forty operated cases there was only one recurrence.

Bumm lays down the following rules to be followed in operating: (1) Defects in the perineum and pelvic floor are best remedied by Hegar's colpoperineorrhaphy. Lawson Tait's method is insufficient and carries with it dangers of embolism. (2) The descended or retroflected uterus must be anteflected, preferably by Alexander's operation or ventrofixation. Vaginal fixation causes permanent discomfort. (3) The best permanent results follow total extirpation combined with anterior and posterior colporrhaphy. Indications for total extirpation in women near the menopause are: (*a*) Extensive prolapse with enterocele; (*b*) chronic metritis, erosions and ulcerations; (*c*) disease and tumors of the adnexæ; (*d*) unsuccessful former operations; (*e*) cystitis which cannot heal owing to the cystocele present.

According to Mackenrodt the connective tissue atrophy is due to changes in the pelvic ganglia after trauma due to parturition. Tearing of the levator ani alone cannot be the cause, since wounds here readily heal without any further results.

In accordance with his theory as to the origin of prolapse, Theilhaber pays no attention to the uterus itself but extensively resects the anterior vaginal wall. The posterior wall is operated only where there is also a large rectocele. In primary prolapse, he seeks to fix the uterus merely by narrowing the vagina.

Gebhard describes his method of vaginal ventrofixation. In uncomplicated cases the duration of the operation is only twelve minutes. One of his cases passed through a normal birth and a second is seven months pregnant. He uses a special needle which can be readily procured.

Asch inquires if there is any method which will posi-

tively guard against recurrence. He believes that general treatment is of as much importance as local. If the condition reappears with a subsequent delivery, it must not be regarded as a recurrence since the original causes are then again active.

DODERLEIN speaks at length upon the cause and prevention of puerperal fever. He believes the hands are the most frequent transmittors of germs and warmly recommends rubber gloves in obstetrical practice.

BUMM found that streptococci occurred in the vaginal secretion of 75 per cent. of pregnant women, in a series of primiparæ the figures were even as high as 86 per cent. The tampons used for checking hemorrhage contained the germ in 70 per cent. and the lochial secretion during the puerperium was always infected. The vaginal streptococcus could be distinguished in no way from the ordinary streptococcus of sepsis, though it seemed to be harmless in all cases examined but three. The only explanation possible is that of diminished virulence. The presence of many streptococci on microscopical examination always speaks for sepsis.

OLSHAUSEN agrees that a carcinomatous uterus can be removed more radically by the abdominal route, but does not believe that the vaginal method is never indicated since a permanent cure was achieved in 18 per cent. of cases. The extirpation of glands prolongs the operation and does not give the patient much better chances. Removal of all the connective tissue in the pelvis is as yet a dream. Five years must elapse before a patient is pronounced cured, since recurrence occurs just as often between the third and fifth year as during the first years. Latterly OLSHAUSEN resorts to the abdominal route more frequently, but merely for the better isolation of the ureters.

WINTER performed a radical operation in 57 per cent. of all his cases of uterine cancer. In order to ensure early diagnosis and operation he sent pamphlets to all physicians and midwives of his neighborhood with very gratifying result.

Ligation of the afferent arteries in inoperable carcinoma of the neck, was no more dangerous, according to STOLZ than curettage and cauterization.

In the discussion which followed GLOCKNER states that his mortality with the WERTHEIM operation was only 10 per cent. Accessory injuries occurred in 15 per cent. and suppuration of the skin incision in 22 per cent. Enlarged glands were found in 34 per cent., carcinomatous glands in 22 per cent. The number of recurrences during the first year was not half of that following vaginal operation. WERTHEIM believes that it will only take a few more years before the superiority of the abdominal operation is generally conceded. MACKENRODT thinks it is impossible to avoid injuring the ureters in advanced cases operated from the vagina. The vaginal route is indicated only in very early cases of cervical cancer, provided the cautery is very freely used, to avoid implantation metastases. If the glands are not removed, the abdominal method is hardly as difficult as the vaginal.

GLOCKNER speaks upon pseudopapillary ovarial cysts and states that they are characterized by the presence of more solid portions between the various loculi, so that they make the impression of solid tumors. Microscopically these portions are septa formed by epithelial protrusions into the connective-tissue walls of the smallest cysts. The cell secretion is very small compared with the cell-proliferation. In the speaker's seven cases the clinical diagnosis of malignant tumor was made and the second healthy organ was also extirpated.

SEMON employed scopolamin hydrobromate with morphine to produce anesthesia, in 52 operations. On the whole, he is well-satisfied and has never met with any accidents. In order to deepen the narcosis, a few whiffs of chloroform were generally found necessary. The advantages of the combined method are absence of all excitement, small amount of chloroform necessary, absence of pain even for some time after the operation, absence of nausea, vomiting and albuminuria.

KRONIG then demonstrated an ether-chloroform apparatus, combined with a Bennet inhaler.

Based upon 110 gynecological and 17 obstetrical operations, performed with spinal anesthesia, STOLZ states that (1) spinal anesthesia is in most cases sufficient for gynecological cases. Operations upon the external genitals require 0.05, laparotomies 0.07 to 0.08 grams of tropacocaine; (2) the analgesia lasts one-half to one hour and the deeper sensory segments remain anesthetized longer than the higher ones; (3) narcosis with spinal anesthesia is brought about more rapidly and with less excitement than without it; (4) spinal anesthesia is not followed by complications, if 0.05 to 0.07 grams of tropacocaine, dissolved in cerebrospinal fluid are employed.

SCHRÖDER relates his extensive experience with the intertrochanteric diameter in pelvic measurement. He regards it as absolutely without value.

STÖCKEL gave a general review of the different ureteral lesions and their therapy and goes into the details of ureteral implantation. The intraperitoneal method is followed by the best results.

After discussing the historical development of our knowledge of cystitis, BAISCH goes into the details of the clinical symptoms of the postoperative form. In fully 50 cases the *Staphylococcus albus* and *aureus* were found present. Streptococci occur only rarely but there is almost always a secondary invasion of colon bacilli. The germs are derived undoubtedly from the urethra since staphylococci and colon bacilli, invariably occur in the urethra of operated women. A partial freeing of the bladder from its surroundings is all that is necessary to permit the germs to gain access and set up an inflammation. To avoid this, the bladder should be catheterized as rarely as possible. By injecting 20 per cent. borated glycerin into the full bladder on the evening of the operation, the urine will generally be voided spontaneously.

The systematic palpation of the sacro-uterine ligaments permits of an exact topographic-anatomical diagnosis and should form an important part of every accurate gynecological examination, according to the paper of SELLHEIM. These ligaments form the best means of distinguishing between parametritis and intraperitoneal tumors and between intraligamentary tumors and such that have grown into the free peritoneal cavity.

According to HEINRICH, the injection of caustics into the uterus, sets up contractions which may force the fluid through the tubes. He therefore devised a new instrument, which not alone introduces the fluid but also permits it to escape at the os. In corporeal endometritis, HEINRICH prefers 10- to 20-per-cent. solution of formalin, in cervical endometritis, 50-per-cent. solution of chloride of zinc and in chronic gonorrheic endometritis without adnexal disease 1 to 10 per cent. silver nitrate every eight to fourteen days.

That there is a close relation between nose and uterus is the firm conviction of OPITZ. In animals the sense of smell may lead to sexual activity and probably to uterine contractions. The same probably holds true to a less extent in man and dysmenorrhea accompanied by abnormally severe pains may possibly be a reflex neurosis starting from the nose.

AMANN believes that vaginal instead of abdominal operations are often performed because abdominal ruptures are feared. It is of the greatest importance to

bring together the muscles and fasciæ after a laparotomy and the nutrition and innervation of the muscles should not be interfered with. A special suture is mentioned which has given excellent results during the last seven years.

Schaller recommends large doses of castor oil for post-operative ileus.

The final paper was by Burckhard, who spoke at some length upon the retrogressive changes in the puerperal uterus of the mouse. The placental site is again covered by epithelial cells by the active mitosis of the cells covering the surrounding mucous membrane. The glands which have lost their connection with the lumen send off new diverticulæ, which are at first solid and later develop a lumen and open upon the free surface.

## SOCIETY PROCEEDINGS.

### NORTHWEST MEDICAL SOCIETY OF PHILADELPHIA.

*Stated Meeting, Held July 14, 1903.*

William Egbert Robertson, M.D., in the Chair.

**The Etiology of Cholelithiasis.**—This paper was read by Dr. Wm. Egbert Robertson, in which he gave a résumé of the history of this condition, stating that but very little had been learned of its etiology since it was first mentioned, about 1570 or 1580. He referred to the fact that obstruction of the common duct would give rise to jaundice, may or may not produce colic and may be discovered only at the post mortem. The stones may vary in size, color, shape and weight, and a catarrhal condition of the gall-bladder and ducts usually precedes the formation. Elevation in the temperature of the liver may give rise to the formation of these concretions, as may also paracelsis, and deposition of the bile salts. The paracelsis may occur as a result of errors in diet, and is frequently due to faulty metabolism. The complications of the possibility of perforation and escape into the peritoneal cavity, and develop peritonitis, or else ulcerate in the intestines were also known. He went into some detail as to the composition of gall-stones, and referred to the fact that when they occur in numbers they are apt to be faceted. He believed that they grew by the addition of strata after strata, which accounted for the indifferent substances sometimes found in different layers of the same stone. He referred to the fact that conglomerate stones are not common in human beings but are not at all rare in animals. He also called attention to the possibility of the formation of these stones in the ducts from the fact that they had been found in animals without any gall-bladder. He referred to the fact that micro-organisms could always be found in these cases and believed that in many instances the formation of the gall-stones could be directly traced to the micro-organism and the consequent deposit of the bile salts and other matters in the gall-bladder and ducts forming the stones, aided by faulty metabolism and gastro-intestinal disturbances.

**Diagnosis of Gall-bladder Disease.**—Dr. J. Thompson Schell read a paper with the foregoing title. He said that the disease depended (1) on the location of the inflammation of stone; (2) on the degree and character of the inflammation; and (3) on the size of the stone, the symptoms varying from those of pronounced jaundice to obscure and in some instances no symptoms at all. Acute catarrhal jaundice, with history of gastro-intestinal disturbance, bile pigments in the urine, slow pulse and no symptoms pointing to acute yellow atrophy or malignant disease, occurring in young adult life is probably one of the most characteristic cases. When the symptoms occur in a patient over thirty years of age, pain similar to gall-stone colic may be caused by the expulsion of plugs of mucus, which can probably be detected by washing the stools, although some assert that the gall-stones may be dissolved in the intestines. Chronic catarrhal cholangitis may be caused by obstruction of the common duct either by gall-stone, malignant disease or pressure on the outside, and may extend into the minutest ducts of the liver. The important symptom is continuous jaundice and the course of the infection is that of hypertrophic cirrhosis. Suppurative cholangitis usually follows upon an attack of catarrhal inflammation, and is usually associated with gall-stones, either in the ducts or bladder. The symptoms are remittent chills and fever, grave constitutional symptoms resembling sepsis, enlargement of the liver, colicky pains and jaundice, which are not so marked as in the catarrhal form. In both forms the blood should be examined to exclude the possibility of malaria. This disease is often difficult to differentiate from abscess of the liver. In abscess of the liver, there is progressive and rapid emaciation and anemia, extreme tenderness over the liver, high and intermittent temperature, rarely jaundice; in suppurative cholangitis, there is a history of biliary colic, transient jaundice and no enlargement except in severe cases, while in abscess of the liver enlargement is a prominent symptom. Cholecystitis he divided into three classes, acute, subacute and chronic, with or without associated gall-stones. The acute variety is usually caused by micro-organismal infection, and he believed the differentiation between the calculous and the non-calculous forms to be possible, but as operative treatment would be demanded in any event, felt that the distinction was of little importance. The symptoms are acute paroxysmal pain in the right hypochondriac region, sometimes in the epigastric or iliac region, followed by nausea, vomiting, abdominal distention, rigidity, tenderness and constipation. The diseases most frequently mistaken for acute cholecystitis are acute intestinal obstruction, appendicitis, acute pancreatitis and perforating gastric ulcer. If the patient has a marked temperature rise, intestinal obstruction can usually be excluded, as the temperature does not usually rise in that condition prior to the development of peritonitis. As to appendicitis, this is the most difficult condition to differentiate and frequently can only be accomplished by an exploratory incision. In acute pancreatitis the pain is usually more and is on the left side, instead of the right, and tenderness, or a tumor, when present, is more superficial in cholecystitis than in pancreatitis. The location of the pain and rigidity are the only differentiating guides between cholecystitis and perforating ulcer of the stomach or duodenum. Cholelithiasis occurs mainly in women—sixty-five per cent. to seventy-five per cent. of all cases usually between the ages of forty and sixty years and rarely under twenty-five years, gormandizing, sedentary occupation, constipation, tight lacing, all act as predisposing causes. The premonitory symptoms, such as constipation, flatulency, loss of appetite, vertigo, tinnitus aurium, migraine, icteroid tinge and scanty dark urine should be carefully considered, as should also the character of the pain, the presence or absence of vomiting and shock, and the condition of the pulse and temperature. Jaundice is an unreliable symptom, and while the urine usually shows bile pigment, it will not do so unless there is some jaundice present. In obstruction of the cystic duct, unless it is absolute, no discoloration of the symptoms may occur. The local physical signs are of great importance and must be carefully considered. Tumor of the gall-bladder, when present, is a great help in making a diag-

nosis. In acute obstructions of the cystic duct a typical tumor is usually found, being round, smooth and elastic and when palpated and pushed away from the abdominal wall will return to the examining finger as if swung on a pendulum. In chronic cholecystitis with adhesions one will sometimes be able to find an irregular mass in this region. The gall-bladder tumor responds to respiration; crepitis can be sometimes but rarely felt, and if Reidel's lobe can be felt with its sharp edge lying across the tumor it is pathognomonic of gall-bladder disease. Among the conditions which we are frequently called upon to exclude in a diagnosis of gall-bladder disease are gastralgia, non-perforating gastric ulcer, intestinal colic, malarial fever, carcinoma of the gall-bladder and movable kidney.

**Treatment of Cholelithiasis.**—This paper was read by Dr. Wilmer Krusen, in which he divided the treatment into (1) surgical, and (2) medical, the latter being divided into (*a*) treatment during the attack and (*b*) prophylactic measures indicated during the interval. The objects sought during the attack are relief of the pain, relaxation of the spasm in order to permit the passage of the calculi, and limitation of the inflammation and congestion of the gall-ducts and liver, which he recommended be accomplished by (1) morphine and atropine hypodermatically; (2) general hot bath and hot fomentations over the hepatic region; (3) in aggravated cases, ether or chloroform to a mild degree of anesthesia, in order to relieve the pain; (4) digital manipulation and (5) saline purgatives. The treatment during the intervals should be directed (*a*) to the solutions of the gall-stones present and (*b*) to preventing the formation of new concretions. The value of the first method he thought was rather problematic, although the Durand remedy of ether and turpentine, and also olive oil, had been quite extensively used. For the prevention of the formation of the stones, one to two drams daily of sulphate or phosphate of soda, and alkaline mineral waters were recommended. A review of the history of gall-bladder surgery was given and early operation deemed to be imperative for the best results to be secured. After referring to the five different operations, (1) cholecystotomy, (2) cholecystectomy, (3) choledochotomy, (4) cholelithotrity, and (5) cholecysenterostomy, which were open to the physician, he described in detail the process of cholecystotomy, which he felt was the operation for most cases, being the simplest, although the presence of a stone in the cystic duct may render necessary the performance of either a cholelithotrity or a choledochotomy. He felt that the wound should not be completely closed but that a rubber drainage tube should be inserted for eight or ten days after the operation, a few days after which a pad may be placed over the sinus, and if bile appears in the stools, a firm pad and strapping will aid in early closure. Cholecystectomy he believed had certain advantages, viz., (1) a radical cure of the cholecystitis and gall-stones by removal of the nidus of infection and calculi; (2) avoidance of biliary fistula; (3) a perfectly clean operation with no soiling by infected bile; (4) avoidance of adhesions; but he felt that the great mortality reported by this operation was a powerful argument in favor of the more conservative procedure, except in cases where the gall-bladder is the seat of suppurative changes, or neoplasms, or when the cystic duct is permanently obstructed. In cases of common duct obstruction, when the removal of the cause is impossible, such as cancer of the pancreas, then the union of the intestine to the gall-bladder, as suggested by von Winiwarter, is of advantage. Five cases were reported, the first being a case of spontaneous rupture of the gall-bladder, after about a week's illness of pain and swelling in the hepatic region, biliary vomiting and moderate rise in temperature, during which time salines and calomel had been administered. A cholecystostomy was done, the cavity cleaned out with gauze sponges; the gall-bladder incised and irrigated and a quantity of biliary sediment evacuated; drainage established for about ten days, and the man made a good recovery. The second and third cases were both those of stones impacted in the cystic duct and both had been primarily diagnosed as appendicitis. In each case four gall-stones were removed, and in each instance one was impacted within the duct; a drainage tube was inserted in each case and both made good recoveries, although one was complicated by an attack of biliary fever, lasting about a week, with a temperature of 103 to 104° F. In the fourth case, appendicitis had been diagnosed, but upon opening the abdomen, no disease of this organ was discovered and the wound was closed without further investigation. Two days later the symptoms had increased in severity, the temperature was 103 to 104° F.; pulse 140; evidences of beginning peritonitis were present and there was a distinct mass perceptible in the gall-bladder. Immediate operation was performed; empyema of the gall-bladder discovered, the pus evacuated and 420 gall-stones removed, but the patient died in a few hours. The discussion was opened by Dr. H. C. Deaver. He believed that the infection was in most instances mild in the beginning, and that frequently cases complaining of vomiting and pain in the upper portion of the abdomen would be found upon careful examination to display more or less tenderness and rigidity in the region of the gall-bladder. Previous history he believed to be an important factor in the diagnosis, but jaundice is so often absent that but little confidence can be placed therein. The differential diagnosis between appendicitis and cholelithiasis is sometimes difficult, but in the latter condition, the fever and vomiting are usually more persistent than in the former. Chronic obstruction of the gall-bladder or enlarged gall-bladder is sometimes mistaken for movable kidney. He believed that the cases that could be benefited by medical treatment were the cases that were diagnosed early, and if the stones were already in the bladder, medical treatment was not only useless but to delay radical interference was dangerous.

Dr. Samuel Wolfe remarked on the fact that there seemed to be very few statistics in this disease from American workers. In the formation of the gall-stones, he believed there were two elements present: (1) A local inflammatory element and (2) a constitutional element, which he felt was evidenced by the fact that gall-stones were more frequently found in people in whom the functions of life were not being very actively performed. In regard to the relation of carcinoma, he felt that probably the carcinomatous condition of these parts was more often the cause of the gall-stones than were the gall-stones the cause of the carcinomatous conditions. In the diagnosis of the condition, he believed careful abdominal inspection and palpation, paying particular attention to any tenderness or rigidity would lead to an early diagnosis in many of the cases. Medical treatment, other than prophylactic, he believed, was of no avail.

Dr. Charles S. Barnes referred to the fact that Ricketts, of Cincinnati, recommended the opening of the duodenum when the stones were impacted in the common duct. He also referred to the importance of early recognition of the condition and prompt operative treatment and referred to the practice of Dudley, of New York, of aspirating the bladder and injecting formalin in infective cases.

Dr. T. Turner Thomas did not believe that if the

gall-stones were the result of infection they could be present without some signs of sepsis. He felt that gall-stones which are local in origin are the results of infection, but that those that are of constitutional origin are the direct results of inflammation or irritation in the gall-bladder. In regard to the diagnosis of gall-stones he called attention to the fact that the classical symptoms are sometimes absent, and particularly is this the case with jaundice. Operation, he believed, should be done early. He referred to the exceedingly small mortality of the operations, varying from about 15 per cent. in the hands of the average operator to as low as 1 per cent. reported by Mayo Robson and Corey. He referred to the difficulty of differentiating between enlarged and movable kidney and gall-stones, abdominal colic, pain and gastro-intestinal disturbance being present in both. In movable kidney, however, the pain extends down toward the testicle, while in gall-bladder disease it extends up the back and toward the right shoulder, and rigidity and pain are important factors in diagnosis.

Dr. William E. Parke laid especial stress upon the importance of early diagnosis and operation, and even although the exact condition present was not diagnosed, he believed an explanatory operation was warranted. He reported the case of a woman aged fifty-one years, who had suffered from severe abdominal pain, necessitating the employment of hypodermics and the icebag. The pain was relieved in a very short time, and she got fairly well, with the exception that she had a most persistently coated tongue. The case was viewed as appendiceal colic, and operation expected to be performed later. About two weeks later a similar attack occurred; there was no jaundice and nothing could be felt except rigidity. She was treated medically by salines, etc., for three or four weeks, without relief, when the conclusion was reached that she was suffering from gall-bladder disease and operation advised. Upon opening the abdomen a cancerous nodule was found in the liver, and the patient gradually grew worse and died.

Dr. Wm. Egbert Robertson in closing stated that the reason the statistics were so much greater from Europe than in this country was due to the fact that the opportunities for post-mortem work were much greater.

Dr. J. Thompson Schell reported the case of a woman four months pregnant, who gave a history of repeated attacks of gall-stone colic. She suffered from abdominal pain, rigidity and the movable mass in the region of the gall-bladder, which had been diagnosed by the attending physician as gall-stones. The abdomen was opened and a small ovarian cyst about the size of an orange removed, since which time there has been no evidence of gall-stones or any trouble whatever with the gall-bladder.

## PHILADELPHIA OBSTETRICAL SOCIETY.

*Stated Meeting held May 7, 1903.*

The President, J. M. Fisher, M.D., in the Chair.

**Exhibition of Specimens.**—By Dr. L. J. Hammond, who said that many of these specimens casually observed present nothing of unusual interest. They have all, however, to him an unusual amount of interest, because of the complications surrounding at least two of them, making what otherwise seemed to be a perfectly clear condition, one of uncertainty, until the actual condition was revealed at the time of operation. The first specimens he exhibited were two unusually large tubes and ovaries which represent rather unique specimens of gonorrheal pyosalpinx, clinical diagnosis being confirmed upon microscopical finding of the gonococci in the pus removed from the severed end of the tube. It is extremely rare to be able to demonstrate the presence of the gonococci in the pus found in the tubes, this being the first case in which he has ever been able to secure positive evidence. The second specimens are quite unique. They were removed from a woman sixty-two years of age, and, as will be noted, they are unusually large, especially the left one with the anterior surfaces smooth and somewhat irregular in outline, while the posterior surface is ragged, showing adhesions of the entire posterior surface to the parietal peritoneum. It was absolutely necessary to quarry them out from the deep tissues in which the posterior surface was firmly imbedded and adherent. Their stony hardness was most pronounced. Microscopical examination shows them to be true enchondroma. The case is therefore one of bilateral ovarian enchondroma. He has not been able, in a rather superficial investigation of the literature of the subject, to find any authentic case of pure enchondroma recorded. The patient, in addition to the six intra-abdominal growths, had also five enlarged perirectal glands which were in size from that of a nutmeg to a hulled walnut. These have since broken down and presented, microscopically, a few weeks ago, a suspicious appearance of malignancy. They were not subjected to microscopical examination and he cannot therefore positively state their true nature. The patient's health, however, is excellent. The third specimen exhibited, so large that he is unfortunately unable to remove it from the jar, is, aside from being an unusually large fibroid, not of special interest at this stage. It is presented in order that he may bring out an unusually interesting feature in connection with the question of diagnosis that presented itself to him when the tumor was exposed through the abdominal incision, that is, an immense hematoma, which, as will be seen by the dark area over the anterior surface of the tumor, was the first point presenting itself through the abdominal incision, and the question at once arose whether the condition was not one of cyst. Of course, this was readily negatived on tapping, when the true character of the contents was revealed. The diagnosis was fibroma before operation. The patient made an entirely uninterrupted recovery. Another point of considerable interest to me in this specimen is that the anterior and lateral portions of the uterus are alone the seat of this myomatous change. The posterior portion of the uterus seems to be entirely free from the growth. The patient from whom this growth was removed was forty-two years of age and had borne one child nineteen years ago. The next specimen shown, of such great size that it is somewhat difficult to handle, was removed from a woman thirty-two years of age, three weeks after birth of her eighth child, at full term. The case was seen in consultation with Dr. West, who had no knowledge of the patient previous to the present confinement, nor could the patient give any intelligent idea as to whether the growth existed before pregnancy, or whether it sprung up during its course. The only information she could give was that her stomach had been very large for a year or more previous. The entire abdominal walls were stretched to their utmost extent, bringing out very conspicuously the distal veins. The presence of fluid could be determined in about the same way as it would be in a general ascites. None of the usual points of dulness observed in ovarian tubes were present. The flanks were distended as they would be in general abdominal ascites. On the left side and extending as far up and beneath the ribs as could be felt was a hard mass, as is shown in the specimen, extending down to the crest of the ilium, and across to about the median line on the left side. With the exception of the markedly dull area overlying this hardened mass, resembling most noticeably an enlarged

spleen, the entire abdomen seemed filled with fluid from within its cavity. Vaginal examination showed the cervix in a normal condition for three weeks after labor. The vaginal vault was markedly convex outward, and pronouncedly tense. The woman presented the characteristic fascia ovariana so aptly described by Sir Spencer Wells. Though this peculiar expression is also found in cases of long standing abdominal ascites, he had, of course, in mind the probability of its being ovarian cyst, though the large mass recognized as decidedly myxomatous made him undecided, and determined him to give some weight to the thoughts of its being a splenic ascites. Of course, this possibility was at once set aside after incision was made. An unusually long incision, extending from the umbilicus to the pubes was necessary to deliver the sac after the fluid, which was rather thick and chocolate colored, had been withdrawn. The wall of the cyst was adherent throughout the entire parietal peritoneum anteriorly, laterally and posteriorly, also to the liver, transverse colon, stomach, spleen and diaphragm, the intestines occupying but an incredibly small space posteriorly. The growth contained more than three gallons of this chocolate-colored fluid, weighed 110 pounds, and the adhesions were the most extensive that he had ever undertaken to break up. The abdomen was drained for forty-eight hours, the patient making a perfectly natural recovery. This myxomatous mass that is seen occupying the left side of the sac is very like in shape to the spleen. It is certainly interesting to him in showing how excusable it would be to at least give serious thought to the possibility of hypertrophied spleen with ascites, especially when one remembers that this cyst wall was so firmly adherent throughout, above, laterally and below that it gave no symptoms different from what would be found in a general peritoneal ascites. The case was, however, one of left-sided ovarian cyst. The rather ignorant subject from whom the specimen was removed prevented his arriving at any conclusion as to whether it developed during the course of the last pregnancy or had been much longer present. From the extensive and well-organized adhesions, however, he is strongly disposed to the belief that it had probably been present during her former pregnancy.

**Placenta Previa with Transverse Position.—Manual Dilatation.—Podalic Version.**—This subject was presented by Dr. Wilmer Krusen, who cited the following case of placenta previa, which, he thinks, is of sufficient interest to be reported, if only to stimulate discussion upon the treatment of this most serious complication of pregnancy: Mrs. McC., aged thirty-four years, IX-para; was first seen with her physician, Dr. John McCormick, on Jan. 6, 1903. The diagnosis of placenta previa had already been made. The patient had been bleeding irregularly for five weeks. Her general condition was good, and the pregnancy was about at term. The hemorrhage had been quite profuse. On examination, the fetus was found in a transverse position; head to the left of the mother's abdomen and the back anterior. The cervix was softer and more succulent than usual. The os was slightly dilated, so that little difficulty was experienced in passing a finger through the cervical canal and feeling the characteristic sponge-like placental tissue above. As the patient had refused to enter any maternity hospital, it was determined to treat the case at her home as well as the environments would permit. On January 7, under ether anesthesia, after the usual careful antiseptic preparation, rapid manual dilatation and podalic version were performed with speedy delivery of the child. The dilatation of the os was easily accomplished, as the woman had borne nine children and had a roomy birth canal. The hemorrhage during the detachment of the placenta, which was centrally implanted, was exceedingly profuse. A gush of blood, resembling the outpouring from a fireplug, deluged the obstetrician. The right anterior leg was brought down first, followed in a few seconds by the other, and the buttocks temporarily controlled the hemorrhage. The child was speedily delivered, although in extracting the arms the right humerus was broken. As the uterus was much relaxed the placenta was immediately delivered manually. The anesthetic was withdrawn and by vigorous external and internal manipulation, by irrigation with hot normal saline solution and a tampon of iodoform gauze, uterine contractions were excited. The patient's condition was excellent, no shock was noted, the pulse was full and strong, running from 75 to 80. The child was perfectly developed and although slightly asphyxiated, was easily resuscitated. As the mortality for the children in placenta previa is over 50 per cent. and increases as the placenta is more centrally situated, the saving of the child was particularly gratifying and could not have been secured, had there been the slightest obstruction or delay in delivery, as the placenta was perforated and almost completely detached some seconds before the birth of the child. The subsequent convalescence of both patients was uneventful. This case illustrates the value of terminating pregnancy in a most conservative manner as soon as possible after a placenta previa has been positively diagnosticated, without waiting for the onset of labor, or subjecting the patient to the danger of hemorrhage in the absence of a physician. By having trained assistance and all facilities at hand for the treatment of hemorrhage and shock, the best interests of the patient are assured. In this case the multiparity of the patient and the roomy birth canal rendered the manual dilatation extremely easy. In other patients, under other circumstances, it may be necessary to employ some mechanical method to effect dilatation such as the Champetier de Ribes balloon or the Bossi dilator; but he believes it will rarely be advisable to perform Cæsarean section in the treatment of these cases.

Dr. Stricker Coles, in discussing this subject, said he was very glad to hear of the success of Dr. Krusen with his case of central placenta previa, having saved both the mother and the child. This subject has greatly interested him for some time, but he has not been able to get satisfactory statistics, as most papers do not clearly define the different varieties of placenta previa. The mortality of the lateral, marginal and partial varieties should not be considered with that of the central variety. The first three can be treated by rupturing the membranes and saving in many cases both the mother and the child, so that he will limit his discussion entirely to that of central placenta previa. In a great many cases of central placenta previa, the bleeding comes on early, at about the fifth month, before the child is viable, and in these cases the life of the child is of course not to be considered, and the case is best treated by version and slow extraction. In cases where the child is viable one comes across two conditions: The first is where there has been considerable hemorrhage and the life of the child is lost or so nearly lost that a radical operation would not be justifiable, and these cases would be best treated with version and the slow extraction of the child. But in those cases where the child is viable and nearly at term and there has not been a severe hemorrhage and the child is in good condition, one has to consider both the life of the child and that of the mother. He believes in treating these cases, if the patient is a multiparous one, where the cervix can be easily dilated and the vagina is large, these cases would probably be successfully treated with version and rapid delivery, trying to save both the mother and the child: but one must always remember that

where rapid version is done and attempt is made to save the life of the child, at the same time the danger to the mother is increased, due to the lacerations of the cervix, which is soft and vascular and will increase the danger of post-partum hemorrhage, because the muscle fibers of the cervix have been torn and paralyzed. Central placenta previa does not very often go to full term, but if he should see a patient with the central variety where the cervix is not easily dilated and the vagina is small, whether it be a primiparous patient or one that has had only two or three children, he should certainly advise such a patient to have Cæsarean section, and for two reasons: First, for the sake of the child, as one will hardly be able to deliver the child quickly enough to save its life in more than 25 per cent.; and second, for the mother, to lessen the danger of post-partum bleeding. He would in this case do celiohysterectomy unless there were some special reasons for the removal of the uterus. Where the child is removed through the uterus, there is not so much danger of hemorrhage, as the cervix has not been torn, and he does not think it is necessary in these cases to remove the uterus. If necessary to control hemorrhage, one can pack the uterus with iodoform gauze. In conclusion, version should be performed in those cases where the child is not visible, and where the child is dead, or its life is endangered from severe hemorrhage, and where the cervix is easily dilated and the vagina is large. In those cases where the cervix is not so easily dilated and the vagina not large, and the woman has not had a severe hemorrhage and the child at or near the full term of gestation—under such conditions, he thinks, Cæsarean section should be employed.

Dr. George M. Boyd said that Dr. Krusen is to be congratulated upon the result in this case. To deliver a patient with central previa successfully and with a living child, he thinks is a great feather in his cap. It shows his dexterity and ability in performing version. He agrees with Dr. Coles in regard to the treatment of a few cases of placenta previa that will come under their care; that is, treatment of placenta previa centralis by Cæsarean section. About a year or two ago he expressed his opinion on this subject in a short paper before the County Medical Society, and he remembers, in the discussion of that paper, the consensus of opinion was opposed to Cæsarean section for even placenta previa centralis. Each case, he feels, must be a study in itself. In marginal placenta previa, manual dilatation and podalic version, it seems to him will serve best. In his own experience it had seemed wiser, after performing podalic version, to treat that case as a breech presentation rather than rapidly extract the child. For the majority of cases of placenta previa manual dilatation and podalic version will serve best. He agrees with Dr. Coles in the stand that he takes: it does seem to him that there are a few cases that probably would be better treated by Cæsarean section; and those few cases he would limit to central implantation of the cervix in the primiparous patient and in a patient where there exists a rigid cervix—a cervix that can only be dilated with difficulty. There have been a number of papers written upon the subject pro and con, and the majority, he thinks, have opposed section for the treatment of placenta previa. One criticism has been the fact that in the majority of cases there has existed some hemorrhage before one sees the case. Another criticism is that some cases are already infected. Another is the fact that in many of the cases the pregnancy is not at term and the child will hardly live, even if delivered by Cæsarean section. The course that he believes should be followed in all cases of ante-partum hemorrhage should be with the first hemorrhage to anesthetize the patient and make a careful diagnosis. If the patient is suffering from a marginal or lateral implantation, manual dilatation and eversion will suffice; if, however, the placenta is centrally implanted and the patient primiparous, the cervix rigid and difficult to dilate, the patient at term or near term, he would feel it his duty, after she has come out of the ether, to place the situation plainly before her and give her the chance of Cæsarean section should she prefer that operation.

Dr. Oliver Hopkinson said that Dr. Krusen must be congratulated upon the happy ending of his case. He believes in placenta previa the lives of the mother and child are antagonistic; trying to save both, you are apt to lose both. He would like to ask the Doctor how he made the diagnosis of central placenta previa, which he thinks can only be made after full dilatation of os. The treatment in cases of the variety described to-night is version followed by slow extraction. He believes it safer to bring down one foot only, giving the uterus time to contract and retract. The great temptation in these cases is to hurry extraction, producing a post-partum hemorrhage, which may seriously jeopardize the life of the mother. In reference to Cæsarean section he thinks its field of usefulness is very limited. With rigid os and mother and fetus in good condition it could be considered, especially if one fears a centrally located placenta.

Dr. L. J. Hammond said his experience in the treatment of post-partum hemorrhage has been rather larger than he expects it will ever be again; since his work nowadays is not so largely obstetrical; but the difficulty he has always experienced has been in the early diagnosis of placenta previa—in this respect fully agreeing with what has been said by Dr. Hopkinson; or at least with him it is extremely difficult, and in a large percentage of the cases it has been impossible for him to say that any given case was one of placenta previa, either centrally or laterally, until after the cervix was dilated sufficiently for him to determine it by digital examination. When he finds he has a condition to deal with of placenta previa he at once anesthetizes the patient and undertakes a rapid dilatation. He has never found any difficulty in getting rapid dilatation, because in every case, to the best of his recollection, that he has ever seen, it has been at full term, the woman having been in labor has consequently lost considerable blood, and through having lost this blood the tissues are readily relaxed, enabling dilatation, not alone of the cervix, but also of the entire birth-tract to be decidedly easy of accomplishing. Before active uterine contractions begin the bleeding can always be controlled by thoroughly tamponing the vagina with sterilized gauze. This, in addition to controlling hemorrhage, stimulates active uterine contractions. So, he has never had any difficulty in this direction, *i.e.*, in the dilatation. If uterine contractions are not strong, he, after securing the feet, brings one foot down as a tampon, after which he contents himself to wait until the cervix is sufficiently dilated to extract the child. He has never, to the best of his recollection, had a fatal termination from placenta previa. He has seen one or possibly two fatal cases when students had been in attendance, the condition not having been recognized sufficiently early. In his own practice he does not remember ever having lost a case, and that has been his method of procedure. Personally, he does not see how it is possible to make a diagnosis weeks or months before the labor begins, unless the cervix be dilated to such an extent as to precipitate labor prematurely.

Dr. Krusen, in closing, said he would like to say one or two words about the case in point. This patient was a very favorable case. She was one of those Irish women, in the habit of having their children easily. The babies had been almost ready to drop out of the birth

canal. The delivery was performed in three or four minutes. The legs could be grasped with the greatest of ease. There was no particular skill required in perfecting version. As to why he is certain this case was one of central implantation—it being suggested by Dr. Hopkinson as possibly an error in diagnosis—the method of making the diagnosis was something like this: In dilating the cervix, the more he dilated the more he found that the orifice was covered with the placenta. He started in with gradual dilatation, getting one finger in early, and later the entire hand and found as he dilated the os, the os was still covered with placental tissue; so he felt confident of his diagnosis. At last he despaired of getting around the edge of the placenta and so perforated it and quickly accomplished the version. In regard to teaching the Cæsarean section as a method for treating placenta previa, he thinks they should be very careful as an obstetrical society. In the hands of such accomplished obstetricians and operators as Dr. Coles, Dr. Boyd, Dr. Hopkinson and others, this is practically a successful method of treatment; but, if they put themselves on record as advocating the treatment of placenta previa by Cæsarean section, they are going to sacrifice not only the lives of the children, but very often the lives of the mothers. When they can have statistics presented showing 107 cases in one series by four practitioners with only one death, it is a question whether they ought to advocate this method ever in the treatment of placenta previa. To go back again, these very gentlemen admit themselves it is impossible to make the diagnosis of a central implantation. If they can show the case is a primiparous woman and has a centrally implanted placenta, then Cæsarean section is indicated; yet, in the next breath they tell us, "You can't tell the variety until labor starts." Now, for the point to which Dr. Boyd called attention, the one point which covers the whole substance of the matter; that is, that each case is a law to itself. One may have a case in the maternity hospital with all the modern appliances; one may have one in a little two-story house, another away off in a farm-house. In each case you must serve the interests of both the child and the mother by using the method best adapted to that particular case and its environment.

**Uterine Fibroma Near the Menopause.**—This was the subject of Dr. George Erety Shoemaker, who said that the medical heresy is passing away, that fibromas grow less, stop bleeding, or do not develop at the time of the menopause. An experience of many years in dispensary and hospital has failed to show a case. On the contrary, peritonitis, pyosalpinx, pressure on urinary organs, hemorrhage kill or forever impair vitality in many who are waiting for a menopause which never comes. Three more cases illustrate onset of severe symptoms after the age of forty-four years:

*Case I.*—Widow, aged forty-four years; married ten years; never pregnant. Within three years periods have become almost constant. Last two months in bed from severe hemorrhage, getting worse. Hemoglobin 45 per cent. Tumor choked pelvis, reached three inches above navel. Removed by ligation. Aseptic recovery. A year later reports herself "splendidly well."

*Case II.*—Single woman, aged forty-seven years. Hemorrhage increasing under her physician's treatment, two years. Now soaks 10 to 12 large napkins per day during long and frequent periods. Dyspnea. Chronic interstitial nephritis. Has had phlebitis in legs and thighs. Weight 215 lbs. Very short. Tumor five inches in diameter wedged in pelvis. Removed by difficult ligation. Aseptic recovery.

*Case III.*—Widow, aged fifty-one years; three children. Hemorrhage gradually increasing seven years, now almost constant. Fibroma reaching three inches above navel. Operation by ligation easy. Aseptic recovery.

These cases are part of a consecutive series of 19 hysterectomies at the Presbyterian Hospital without a death; also part of a consecutive series of 60 abdominal operations in my service at the same institution, with one death. That death followed a few hours after operation for intestinal obstruction in a patient who had been vomiting thirteen days before I saw her, and had gangrenous intestine with extensive adhesions. The operations included 1 Porro-Cæsarean section, 14 other hysterectomies, 2 extra-uterine pregnancies, a gall-bladder and two kidney cases. The appendix was removed 20 times, 6 of them as a primary operation. Nineteen cases had salpingitis. Pus was present 18 times at the operation, six of these as true pelvic abscess outside the tubes, and not due to appendicitis. There were two tumors of the ovary, etc. Once only was the abdomen opened to suspend the uterus.

Dr. L. J. Hammond said that the cases reported by Dr. Shoemaker are interesting to the Society, especially to the surgeon; and he is to be especially congratulated upon having had so large a series of cases, with practically no mortality. He knows so well the difficulties one encounters in removal of these fibroids, and in fact, most every intra-abdominal pathologic condition. Every year he finds that his work becomes more difficult, and most every case that comes to him seems to bring additional complications to what they did a few years ago. Just why it is so he does not know, unless it be that the easy cases have all been used up—have all been operated on and cured. Within the past few months he has had a series of the most difficult intra-abdominal cases to operate upon that he has ever before had because of the extensive adhesions, etc., that he has had to deal with. These cases referred to by Dr. Shoemaker as being partly intraligamentous are always very difficult; they are difficult to him because of the great depth that ligatures have to be tied and the hemorrhage that one has to deal with so very often, the result of this, and especially if there be, as there so often is, extensive adhesions. He would like to hear from Dr. Shoemaker as to whether these intraligamentous tumors were extensively adherent and his method of securing the vessels under such conditions.

Dr. Geo. M. Boyd said that in one of the cases that Dr. Shoemaker reported he told them that the tumor completely filled the pelvis. He would like to ask Dr. Shoemaker what operation he resorted to in that case. In his experience those cases have been probably the most difficult to operate upon. The course that he has pursued is to tie down upon one side and, boldly cutting across the cervix, ripping the tumor out, catch the bleeding vessels. To tie down on either side before removing the mass has always been a difficult course for him to pursue.

Dr. Krusen said the thought came to his mind while Dr. Shoemaker was reading his paper about how much more radical operators have become in the treatment of fibroid tumors. There seems to be a tendency in recent medical literature to deal with the degenerative changes in fibroid growths. Formerly many specialists told their patients that if they had small fibroids and were near the menopause, operation was not required; but there have been a number of articles contributed lately, and much work has been done by pathologists showing the frequency of sarcomatous degeneration, and this possibly will lead us to teach in the future that fibroid growths should be removed as soon as recognized, whether they are producing marked symptoms or not.

Dr. Shoemaker in closing said he would say in the cases that have not had inflammatory complications he has not generally had a leucocyte count, as he has never

found anything helpful from it under such conditions; but he always has a hemoglobin estimation. Some of these cases have been reduced to a very low point by hemorrhage. They are obliged to temporarily control hemorrhage while they can bring the hemoglobin up to a reasonably safe point. To do this he uses tight vaginal gauze pack with the patient in the knee-chest posture. Renew every third day. He gives mammary extract, five grains four times a day and keeps them in bed. Ice is put on if there is local peritonitis until the patient is in better shape. As to the method of removal, when the tumor is intraligamentary on both sides, he thinks the best they can do is to go down with forceps and ligatures on the best side, and cut away the tumor as fast as possible, catching the arteries as they jump. That is what happened in this stout woman. There is a little more blood lost that way, but one cannot give tumors which choke the pelvis treatment, which is more satisfactory as far as he can find. He has never felt like going down through the tumor with the uncertainty of being able rapidly to ligate.

**Exhibition of Specimen of Fetus Papyraceus.**—By Dr. Stricker Coles. For this case he is indebted to Dr. J. H. Spruance, of Wilmington, who also gave him the following history of the patient: The woman was thirty-five years old, she has had three children and three miscarriages; the last miscarriage being two years before this pregnancy. As near as he could count, the patient was advanced three hundred days gestation. The first stage of her labor lasted eight hours, the second stage two hours and the third stage about an hour and fifteen minutes. The placenta and fetus papyraceus was removed by Credé's method. The child was a male weighing eleven pounds and six ounces, was well developed and was in a perfectly normal condition. He found that the specimen which was delivered on January 11 of this year has been placed in a bottle with mouth so small that it cannot be removed. The condition which he wished to especially investigate was whether there was a complete chorionic sac for both the fetus papyraceus and the child. There are always two amniotic sacs, but of course, in many cases there is only one chorion, but this he could not determine. In both cases there is a velamentous attachment of the cord to a single placenta. This is a rarer condition than where there are two separate placentæ. He should say the fetus papyracens had grown to about the period of three and a half months' gestation before death.

## BOOK REVIEWS.

Tumors—Innocent and Malignant. Their Clinical Characters and Appropriate Treatment. By J. Bland Sutton, Surgeon to the Chelsea Hospital for Women; Assistant Surgeon to the Middlesex Hospital, London. Third Edition. W. T. Keener & Co., Chicago.

There are certain general characteristics of this type of English book which impress themselves at once upon the American reader. The most pronounced is that the author's standpoint is distinctly a scientific rather than a merely medical one. In an altogther charming way he has contrived so to mass the vast wealth of material under consideration that logical and easily retained deductions are the rule thoughout. The book is absolutely free from dogmatism and empyricism. In short, its charm and very great worth lies in the fact that throughout, comparative statements are made. This has been most successfully exemplified in those chapters which deal with congenital deformities, but wherever a prototype of any common tumor exists in plant life or in the lower animals, the relationship is most graphically carried out. As a consequence, this volume must be of the very utmost value to all teachers of pathology and allied branches. Whatever regrets, if any, the reader may formulate in following these most interesting and instructive pages must center upon the author's methods of treatment. One can be forgiven for wishing that the public might profit by his being willing subsequently to devote his attention more strictly to the elucidation of the pathological problems which are so difficult of solution. In their interpretation he has few, if any, peers.

On points of surgical technic he would appear from the text to have at least a number. The hope might therefore be expressed that the next edition may deal more largely with the comparative pathology of tumors, leaving their treatment to the hands of the ordinary surgeon. The book is probably without a peer from the standpoint of the pathology, etiology, symptomalology, and diagnosis of tumors.

Of very special import in this edition is the chapter bearing on the deciduomata which are provisionally classified with the sarcomata. Cheering also is the rescuing of the harmless myelomata from the "banal society of the sarcomata." Not less progressive and clearly indicative of the stamp of the book is the elimination from its pages of the term "epithelioma." It is replaced by the phrase "squamous, called cancer." It might be fortunate for the student and for us all if a further expurgation should liberate us from the word *cancer* altogether.

The book is attractively made, the print being particularly clean-cut and readable. Its makers are to be congratulated on having turned out a perfect volume.

Organic Nervous Diseases. By M. Allen Starr, M.D., Ph.D., LL.D. Professor of Diseases of the Mind and Nervous System, College of Physicians and Surgeons, New York; Consulting Neurologist to the Presbyterian and St. Vincent's Hospitals; St. Mary's Free Hospital for Children and to the New York Eye and Ear Infirmary. Lea Brothers & Co., New York and Philadelphia.

Dr. Starr's work comes to the profession with the weight of authority that instantly stamps it as worthy of the fullest consideration and in the present work before us we find one of the most clear and readable textbooks that it has been our fortune to see. Furthermore, a text-book which, from the illustrative point of view, leaves almost nothing to be desired. It is both fully and beautifully illustrated.

Regarding the subject-matter, it may be said that the consideration of neuritis is almost monographic, the author's many studies in this line having placed him in a position of particular prominence. The articles on the muscular atrophy, muscular dystrophy are very full and unusually lucid; while the discussion of injuries of the spinal cord is brief and presents a summary of modern-day knowledge that can hardly be improved upon. As would be expected, the author's consideration of tumors of the brain is especially illuminating. In view of his wide experience, the general conclusions on the unfavorable outcome in the surgical treatment of brain tumors leaves a sense of disappointment of possibilities coming from so high an authority.

The author's very clear and straightforward style renders the work one of special attraction to the student and practitioner. It is clear-cut and direct and the clinical pictures easily recognizable. Treatment is particularly complete and detailed. From every point of view the work is one entitled to more than ordinary commendation.

VOL. 83. NEW YORK, SATURDAY, SEPTEMBER 12, 1903. NO. 11.

## ORIGINAL ARTICLES.

### INFANTILE SCORBUTUS.

BY THOMAS MORGAN ROTCH, M.D.,
OF BOSTON, MASS.

THE following cases of infantile scorbutus are reported for the purpose of impressing upon the profession the great care which should be taken to differentiate between an advanced bone lesion of this disease and the bone lesions which arise in osteomyelitis and osteosarcoma.

*Case I.*—A boy ten months old was sent to the Children's Hospital on February 8. The family history was negative. He was born at full term. He had been fed on cereal milk and gained in weight until the present illness began and had seemed perfectly well.

For two weeks before entering the hospital the right lower leg seemed tender, and four days before entrance a swelling of that limb was noticed. The child appeared quite ill. He was seen in the out-patient department and sent into the house for acute osteomyelitis.

The skin was pale. There was a marked rosary and enlarged epiphyses of both wrists and ankles. There were two lower middle incisors. The gums were slightly reddened about the base of the teeth, but there was no distinct stomatitis ulcerosa. The heart, lungs and abdomen were negative. The prominent feature of the case was the swelling of the right leg from the knee to the ankle, and this was especially marked above the outer malleolus. The swelling was hard, tense and tender. The skin over it was glazed, but there was no fluctuation. The rectal temperature was 101° F. The blood count at the time of the entrance showed 19,200 white cells.

On February 10 the infant was operated upon. An incision was made through the periosteum and a large blood clot found. The periosteum had been completely dissected off from the tibia. A culture taken at the time of the operation was found to be sterile.

On February 18 a second operation was performed on account of the temperature rising to 103° F. The bone was then found to be loose, and the entire shaft of the tibia came out in two pieces.

On February 28 a third operation was performed, as the child was rapidly growing worse. He had run an irregular temperature and had grown pale. There was an ecchymosis of the size of a quarter of a dollar below the left nipple. The other leg (left) was at this time in a condition similar to that of the right leg on entrance, except that the thigh was chiefly affected, the swelling extending from the groin to the calf. A complete blood examination was then made with the following result: Hemoglobin, 50 per cent.; leucocytes, 27,100; erythrocytes, 2,400,000.

A differential count of the white cells showed: Polymorphonuclear leucocytes, 68.6 per cent.; small lymphocites, 23.2 per cent.; large lymphocites, 7.4 per cent.; eosinophiles, 0 per cent.; myelocytes, .2 per cent.; mast cells, .6 per cent.

The erythrocytes showed marked poikilocytosis. During the count there were seen normoblasts, 15; megaloblasts, 5, showing a severe secondary anemia.

The operation consisted of an incision through the periosteum of the femur. A large blood clot was found and the bone was found to be bare. The child experienced little or no benefit from these operations, but grew steadily worse until March 1, when the surgeons called me in to see the case in consultation. I suggested the diagnosis of infantile scorbutus and ordered orange juice. From that time there has been steady improvement in the condition of the child. Additional purpuric spots appeared on March 20 on each side of the neck, and on April 6 all tenderness had disappeared and the periosteal sheaths were firmer, but had not united to the bone epiphyses. The left leg was still somewhat swollen. The blood count showed a decided change for the better. It was: Hemoglobin, 65 per cent.; leucocytes, 17,800; erythrocytes, 5,080,000. Differential count of 500 cells showed: Polymorphonuclear leucocytes, 67.2 per cent.; small lymphocytes, 21 per cent.; large lymphocytes, 5.8 per cent.; eosinophiles, 6 per cent. Red cells showed very slight poikilocytosis. During the count there were seen only three normoblasts and no megaloblasts.

The child's general condition has improved steadily up to the present time. There are evidences of increased bone formation, as shown by the X-ray. The condition of the blood on May 8 was as follows: Hemoglobin, 80 per cent.; whites, 13,700; reds, 5,370,000. A differential count of 400 cells showed: Polymorphonuclear, 37 per cent.; small basophiles, 43 per cent.; large basophiles, 4.2 per cent.; oxyophiles, 12.6 per cent.; myelocytes, 2.3 per cent.; mast cells, .9 per cent. Stained specimens show very slight poikilocytosis and very slight achromia, otherwise nothing remarkable is seen concerning the reds.

This is presented, not only as representing one of the more severe conditions appearing in infantile scorbutus, but also to show how difficult it is at times for the surgeon to differentiate between infantile scorbutus with subperiosteal hemorrhage and osteomyelitis, also the great value which the use of the X-ray is in such differential diagnosis.

*Case II.*—A boy nine months old came to the out-patient department October 3, 1901. He

had been fed for the first five months on Mellins' Food, and for the last four months on Cereal Milk. His birth-weight was 7½ pounds and his weight at the time of the first examination was 9 pounds, a gain of 1½ pounds in nine months. The family history was negative.

The four weeks before entrance he became fretful and irritable and the lower extremities became sensitive. One week later the left thigh began to swell, swellings appeared just above the ankles and a few days later the right thigh became similarly affected. The swelling of the thighs progressed. The mouth was red and sensitive, while the baby was cutting two lower incisors.

On September 26, about four weeks after the onset of the symptoms, the baby was seen in the out-patient department of the Children's Hospital. It was emaciated. The anterior fontanelle measured 1½ inches. There were two lower incisors and there was a general enlargement of the lymph nodes. The gums showed a slight purplish tinge, but no typical stomatitis ulcerosa. There was a marked rosary. The spleen was just palpable and the liver was palpable two fingers breadth below the costal border. The prominent feature of the case was the marked enlargement of the thighs, in contrast to the emaciated body, especially the arms. The swellings extended from epiphysis to epiphysis, being especially prominent anteriorly. There was no limitation of motion in the joints. The swellings were

CASE I. Infantile scorbutus. X-ray.

apparently connected with the bone; they were hard and tense and somewhat tender, but showed no heat or redness. There was no edema of the subcutaneous tissue. Above the left inner malleous was a similar swelling, much less advanced. The blood showed 7,400 leucocytes. There was no pronounced pallor. The right thigh measured 8¼ inches, the left thigh measured 7¼ inches. The treatment consisted of plain cow's milk, properly modified and orange juice.

*Subsequent History.*—There was was considerable difficulty in adjusting the food to the infant's digestion, but the swelling and tenderness of the legs rapidly diminished in spite of the persistence of more or less indigestion. At the end of four weeks each thigh had diminished nearly two inches in circumference and there remained no evidence of any swelling or tenderness. The weight was still 9 pounds, but from that time the baby began to gain on a fat, 2.50; sugar, 6.00; proteids, 1.00; 15 per cent. alkalinity; 10 ounces barley water in a 40-ounce mixture. Six feedings of 6 ounces, gradually increased to 8 ounces.

In seven weeks the infant had gained 3¾ pounds. The food was then rapidly increased in strength and quantity, and in the following March, 4½ months after the beginning of treatment weighed 17 pounds, a gain of 9 pounds.

The history just given was that of an advanced case of infantile scorbutus. There were certain points in the case, however, which are of great significance. In the first place, before the treatment was begun, the right thigh showed not only considerable enlargement, was unyielding to pressure, and so hard that it strongly suggested the presence of osteosarcoma. The case, therefore, was a difficult one in which to make a differential diagnosis, and it had even been suggested by some who saw the case that an amputation for osteosarcoma would be needed. It is presented as a condition, which, without the use of the X-ray and with the absence of other symptoms of scorbutus and apparent lesions in the other limbs which may occur in infant scorbutus, would make the differential diagnosis between osteosarcoma and subperiosteal hemorrhage very difficult.

CASE II. Infantile scorbutus.

## NOTES ON EXPERIMENTAL SURGERY: A MODIFICATION OF THE M'GRAW ELASTIC LIGATURE.

BY J. W. DRAPER MAURY, M.D.,
OF NEW YORK.

THE following report is of work done by the authorization of the Department of Surgery of Columbia University. Its execution was rendered possible by the courteous co-operation of Professor John G. Curtis, who placed the matchless equipment of the physiological laboratory at my disposal and in every way fostered and furthered the work.

It is scarcely possible to consult any authorita-

tive modern article on gastric surgery which does not deal either with the problem of the relationship of gastric ulcer to carcinoma or treat its subject-matter under the assumption that this relationship is established. The most recent views, indeed, hold not alone that ulceration is the most important etiological factor in the production of malignant gastric neoplasms, but that it is the prime causative factor in the development of the so-called "simple diseases" of the stomach. What future observation will determine to be the actual facts in this matter is an interesting question. Enough is now known, however, to make the operative treatment of gastric ulcer, whether in its acute form or in its late and protean manifestations, one of the most important medical questions of the day.

Two widely different operative procedures for the relief of identical gastric lesions have been introduced almost to the exclusion of others: the one is pylorectomy, the other gastro-enterostomy. Opinion is at present divided as to whether in intractable cases of chronic ulceration, more lasting good will be conferred by pylorectomy, which implies a removal of the ulcer-bearing area and a re-establishment of the channel in its normal position, or by the somewhat more conservative operation of gastro-enterostomy, which, creating an entirely new path for the food, puts the pyloric region out of use, places the ulcer-bearing region at surgical rest and allows it to heal. Inasmuch as there are considerations, both immediate and remote, bearing upon the choice of these operations, some of which are as yet of a hypothetical nature, it does not seem probable that either is likely to supersede the other until these questions shall have been set at rest.

Gastro-enterostomy is frequently accomplished by the well-known "Murphy button." The great utility of this instrument is widely recognized, but, unfortunately, its most ardent advocate cannot say that its use is danger-free. In reply to a recent inquiry, Dr. John A. Wyeth writes that he was obliged to re-operate not long since, 120 days after he had used a Murphy button in doing a gastro-enterostomy. After gastrotomy and removal of the button from the stomach the patient died. Numerous similar instances are recorded of disaster due to the retention of the button after it had successfully accomplished its work. Nor is it free, as recorded by Moynihan, from the immediate danger of perforation, quite aside from that of subsquent obstruction. It seems, therefore, important, that some method, equally certain in its action, but less dangerous in its possible sequelæ than this most ingenious device should be contrived. Obviously such a device must "punch out" the juxtaposed parts as freely as the "button," because failure to do this is undoubtedly a factor in permitting the partial or complete closure of the gastric enteric fistula. The ultimate cause of this contraction is not yet known and it offers a very fertile field for investigation.

About ten years ago, Dr. Theodore A. McGraw, of Detroit, described a very simple method of making enteric anastomoses. It consists simply, to quote his own words, of "A Lembert stitch and a ligature." After choosing the parts through which the opening is to be established the operator places a row of Lembert stitches so as to join the surfaces for a distance of about one inch and a half. A stout elastic ligature, threaded on a round needle, is then passed into one viscus near the beginning of this suture line and out near its termination. Similarly, the needle transfixes the opposite organ and the ligature is then tightly tied. The Lembert row is completed and the parts replaced. The elastic cuts its way through in from two to three days. Obviously, neither this technic nor any modification of it could be employed for the relief of complete obstruction, although it is probable that a certain amount of leakage must take place some time before the elastic is liberated. Here again there is need of further observation. There exists, however, a large class of cases in which the establishment of an opening is not an *immediate* necessity, and in which delay may be of positive value.

That the ideal technic is not yet reached and that a spirit of unrest and uncertainty is rife is evidenced by the following quotation from Dr. Geo. R. Fowler: "It may be that further experience will show that the use of McGraw's elastic ligature will prove of use in respect to both the jejunal reflex and the occurrence of shock and collapse as well as the possibilities of infection, since the period of time occupied by the elastic ligature in completing the anastomosis, namely, from forty-eight to seventy-two hours, corresponds closely to that in which vomiting is mostly to be feared, and the rapidity with which the operation can be performed and the cleanliness which it makes possible guard against shock and infection. I confess, however, to a feeling respecting the elastic ligature, akin to that expressed by Codivilla, who, speaking of the use of the Murphy button in gastro-enterostomy, said: 'Its good function is always in God's hands.'"

That the ligature, when applied in accordance with McGraw's technic, gives excellent primary results, however, is hardly to be doubted. It has been practised successfully by men of the highest standing quite aside from the numerous times it has been employed by its distinguished inventor. In a recent letter Dr. McGraw says: "I have heard again from Dr. A. J. Ochsner, of Chicago. He has just operated on his sixth case, the other five having given most satisfactory results."

Are these immediate results to be permanent? Undoubtedly Dr. Weir voiced a general criticism of the method when he said that he had feared to use it because it did not "punch out." He believes that although the opening may be made practically as long as the operator desires, its patency may be effected by the growth of bands forming bridges from one side to the other. This seems a very plausible hypothesis, since, for considerable periods, the raw edges of the slit must lie in apposition, and such bridges, if formed,

would in time narrow the lumen to a useless fistula.

In April last the writer began a series of laboratory experiments which aimed at finding a method so to place the elastic ligature that it *would* "punch out." Rabbits were first used, but they died from shock or from obstruction—the gut being too small to work upon satisfactorily. Dogs, however, reacted admirably, and although, as is well known, successful work with their gut does not always imply that like results will follow the employment of like technic in the human intestine, because of the great dissimilarity of the organs, conclusions of a presumptive character can be reached by this means.

Dr. McGraw kindly furthered my efforts by sending a dozen of his ligatures which are made to his partial satisfaction by Messrs. Nelson Baker & Co., of Detroit. These gentlemen hope shortly to offer an elastic somewhat smaller than the present one and as strong. The ligature now on the market may be described as follows: It is a black circular band, almost a foot long, and so sharpened as to be easily threaded on a flat-eyed needle.

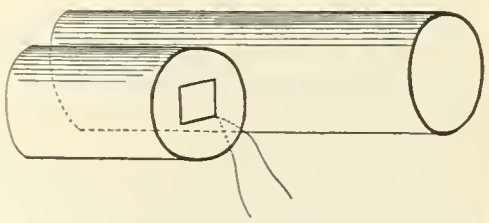
Fig. 1.

Dog's Stomach—one of the early specimens—the bands referred to are seen uplifted by rubber tubes. The lumen in the specimen was larger than is shown in the photograph, where it appears as a small slip because of the presence of the tubes. A cm. scale is appended.

It will stretch over six times its length and is virtually unbreakable with the ordinary force of the fingers.

In the preliminary experiments the elastic was so placed that some excellent results were obtained in that an irregular opening was always made. In every case, however, two bands of tissue stretched directly across the opening—as seen in Fig. 1—two bands of mucous membrane from the gut and stomach pass over two rubber tubes.

Fig. 2.



Crinoline model showing the method of applying the stitch.

The bands are at right angles to each other and partly occlude the lumen. The manner in which this tissue came to be left was never worked out and although each semicircular opening could be made, at will, larger than the pylorus, the technic was evidently defective, though not to be unreservedly condemned.

Mr. Edward Cussler and Mr. J. S. Thomas, both juniors in the medical department, assisted me throughout, and it is a pleasure to state that the further and apparently successful modification of the McGraw technic was made by them. It is a further pleasure to state that without the hearty co-operation of Mr. John T. Hoyt, of the Physiological Laboratory, this work could not have been carried on so successfully.

Fig. 2 shows a sketch of a model in crinoline of the stitch as modified by the students. The point of view is from the mucous surface of either the gut or stomach. The four sides of the rubber square which are seen, lie directly upon four corresponding sides of a similar square in the opposite and juxtaposed organ. How such a stitch can fail to "punch out" as much as may be desired is not clear, although the experiments made are by no means sufficient in number to justify more than conservative claims for it.

If, after passing such a stitch, the parts are gently separated so as to show three of the four corners of the square, it will be seen that at each point and virtually through the same hole the ligature passes twice. If the sides of the square be made 3 cm. long it will be noted that unless the intervening tissues between the angles be held in close apposition, there will be danger of leakage. In using a square form of the stitch, then, it is absolutely necessary to protect the part with a continuous or an interrupted Lembert stitch. If an octagonal form be used, the need for such protection would be more remote because this would double the number of through-and-through stitches and give intimate junction of the apposed serosa, simulating the conditions established by the use of the "Murphy button."

The following is a technical description by Mr. Thomas of the method of inserting the liga-

ture: "It is possible at will to make the opening a triangle, square, hectagon or octagon. A square provides, to all intents and purposes, a circular opening. It was used in all save a few of the later experiments. The detailed technic

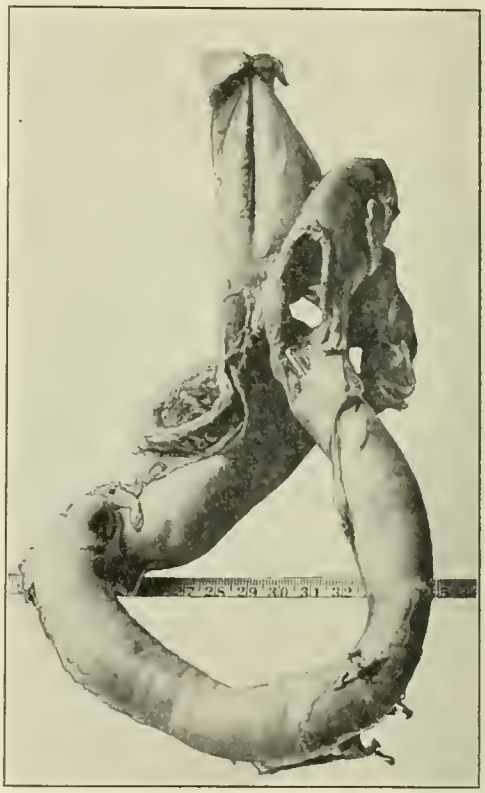
Fig. 3.

Dog's Stomach with section of jejunum attached—the latter split open to show its mucous membrane. The preparation was hardened in formalin—a cork which dropped into the fistula by its own weight having been inserted to prevent shrinkage.

of insertion is as follows: Decide on the size of the square desired, and, after approximating the surface, gut and gut or stomach and gut so that there may be no unnecessary tension, place a Lembert stitch of silk to join the two viscera at each of two points destined to be the diagonally opposite angles of the completed square. These stitches will hold the parts together and will serve as guides for the introduction of the ligature. The needle is introduced into one of the apposed viscera at a point selected for one of the remaining angles and brought out beside one of the guides. From here it is passed through the opposite organ, care being taken that the needle thoroughly pierces the mucous membrane—which is somewhat resistant in a dog but not so in a pig—and out again at a point diagonally opposite the starting place. From this point to the point of beginning the steps are directly reversed, viz.: the needle re-enters the first viscus, emerges at the first guide, re-enters the second viscus and emerges as nearly opposite the starting point as possible. The stitch is then just half done; two sides of the square are completed, and the arrangement of the elastic ligature may be correctly represented by a figure 8 bent in the middle. The remaining two sides of the square are completed in the same manner, care being taken to make the distal loops of the two figures of 8 interlock."

In the earlier work with this stitch the ends of the elastic were tied with fine silk, precisely as recommended by McGraw; but, recently, it being found how firm a knot could be tied with Senn's iodized catgut, and that it would not slip, this was substituted for the non-absorbable silk. No. 2 gut was found to hold the ligature long enough to allow it to "punch out:" then absorption of the gut freed the knot and allowed the elastic to uncoil. The result was simply that the

Fig. 4.

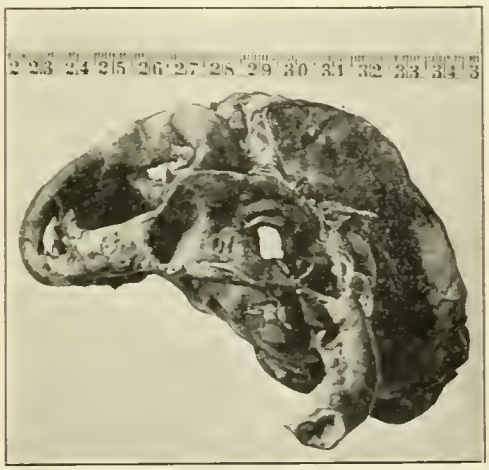


Dog's Stomach showing a small portion of mucous membrane, the pylorus and the attached duodenum. A window has been cut in the gut showing a hexagonal opening into the stomach. This specimen was filled with one-per-cent. weak formaldehyde solution, and the extremities tied. The relations of the lumen to the gut are therefore preserved in just proportion.

ligature, when passed by rectum or when vomited (one case) came out perfectly straight (see Fig. 5), looking much like a bit of old-fashioned slate pencil, 5 cm. long. There may be no merit in this, but a straight piece of elastic in the alimentary canal might be even less objectionable

than one coiled and knotted. Furthermore, it is thought that the liberation of the elastic will be a factor in preventing its adherence to the mar-

Fig. 5.



Dog's Stomach, showing duodenum and quadrangular opening. Size shown by cm. scale.

gin of the fistula as was noted in several cases operated upon by the McGraw technic as well as by our own. This retention of the ligature is a factor which merits further observation, and sug-

Fig. 6.

Dog's Stomach seen from mucous surface. Five openings are shown, three of which are the cut ends of the pylorus and the gut—the fourth being the pylorus, and the fifth, the fistula.

gests the possibility of doing away with the elastic altogether and using heavy iodized gut in its place. This, if practicable, would indeed be ideal—the utilization of an entirely absorbable material which would vanish as soon as its work was done. Further experimentation will determine this point.

The time consumed in taking the stitch varies very naturally with the experience of the operator. To make a square consumes, perhaps, twice the time necessary to place a "Murphy button" or the simple McGraw stitch—probably a little less than the ordinary method of section, excision and double ligation. It appears, therefore, that no objection can justly be made to it, since the time requisite for its performance falls within reasonable bounds. Furthermore, it is no doubt true that if we have had but little trouble in placing the stitch in the tough elastic viscera of dogs, hands more expert than ours should experience less annoyance and less delay in inserting it in the more easily handled human gut. That this may be true is shown by the ease with which the ligature was placed to form a triangu-

Fig. 7.

Dog's Stomach seen from serous surface, showing a very satisfactory opening.

lar entero-anastomosis as well as a quadrangular gastro-jejunostomy in a pig weighing 120 pounds. [The pig is fed on the refuse from the hospital and has since gained eighty pounds.]

Autopsies have been done on seventeen dogs. Three dogs, with the pig, will be kept until fall, to form, if possible, the nucleus of a further report. Of seventeen dogs in which elastic ligatures were placed in a variety of positions; straight, cruciform, triangular and square, some with and some without burying Lambert sutures, six died. One perished from intestinal obstruction due to a band situated at a distance from the site of operation, and probably caused by rough handling; two, in which no protecting stitches whatsoever were used, from perforation at the site of ligature, showing the imperative need of such support; two from pin-point perforations of the gut, due to bad technic, one from sepsis (3½ months) from a localized stitch abscess. While it is not intended that this incomplete report shall form the basis of any mortality comparisons, it is not without interest to note that there were no deaths

in those cases where the ligature was applied in conformity with accepted rules of enteric surgery, which might not have occurred in the execution of any other technique.

From this too small and confessedly incomplete series of experiments the following conclusions suggest themselves:

1. The McGraw Elastic Ligature can be so inserted as to "punch out" as large an area of the juxtaposing walls as may be desired, with at least as much certainty and with greater safety than the Murphy button.

2. That the margins of such openings are smooth and not unduly cicatrized.

3. That the elastic ligature may remain in situ after punching the openings, although this is less likely to happen if tied with iodized catgut.

4. That such retention in the mucosa of so soft a material is not apt to be harmful or permanent.

5. That the time required is not sufficiently increased to render the use of this technic impractical.

6. That perhaps enough has been suggested to stimulate further research by others, so that the actual facts in these most interesting problems may shortly be brought to light.

**Influence of Diphtheria and Tetanus Toxin upon the Blood.**—It was found by H. Kucharzewski (Centralbl. f. Bakt., Vol. 34, No. 4) that tetanus toxin diminishes the number of red cells and the amount of hemaglobin. Large doses also diminish the density of the blood. A hyperleucocytosis is also noted but not so marked as that with diphtheria toxin. It is not to be ascribed directly to the amount of toxin injected, for there is first a period of hypoleucocytosis. The number of pseudo-eosinophiles is increased while the lymphocytes and eosinophiles are always diminished. The proportion of large mononuclears and intermediary elements does not vary from the normal. When the toxic substances were destroyed by prolonged heating, these blood-changes were not noted, which proves that they are solely due to the toxins and not to the culture medium.

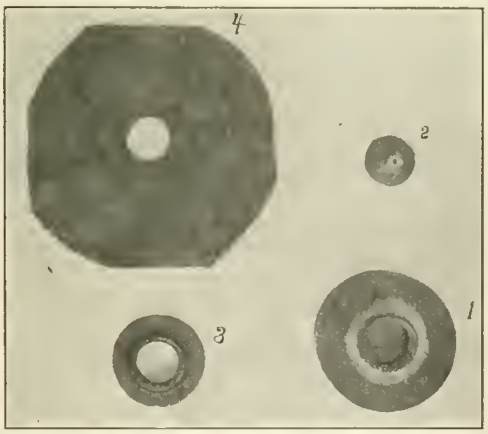
## A PROPOSED APPARATUS FOR THE TREATMENT OF EMPYEMA.

BY FRANCIS M. C. USHER, M.D.,
OF FORT YELLOWSTONE, WYOMING.

In the whole domain of surgery no branch thereof has reaped greater benefit from the introduction of antiseptic and aseptic methods than that part which relates to the surgical treatment of pleural effusions. Nor, indeed, has the application of modern methods of diagnosis secured more gratifying results; what once was in doubt can now be accurately determined by the aspirating needle, microscope and culture tube, and cases which were formerly doomed are now given reasonable hope of cure through proper surgical intervention. One of the first effective steps in this direction was the introduction of the vacuum aspirating apparatus whereby pleural effusions could be drawn off with the minimum risk of introducing air into the pleural cavity and thereby possibly contaminating and changing a simple effusion into a purulent one. In uninfected effusions this method of aspiration, repeated if necessary, will very frequently effect a cure, especially in the young. In infected effusions, however, the procedure in the end must be radically different; pus in the pleural cavity like pus anywhere else, must have free and continuous drainage before an effective cure can be hoped for. This of course necessitates an opening into the pleural cavity and establishing free communication with the outside air. The moment, however, that the visceral layer of the pleura is subject to the constant pressure of one atmosphere there arises a purely mechanical problem which has been but unsatisfactorily overcome, and which in itself is the prime cause of the unsatisfactory results following thoracotomy and the subsequent performance of the mutilative but necessary thoracoplastic operations. The lung containing elastic tissue, on the stretch at all times except in forced expiration, maintains a pull of about one-quarter pound to the square inch on the inner chest walls and diaphragm, which, being air-tight and sufficiently rigid, hold the lung in apposition to them. When an opening is made in the chest wall this negative pressure between the two layers of the pleura no longer exists and the lung is free to contract to the extent of the contractility of its elastic tissue. This it does when a thoracotomy is done for the purpose of drainage of pus. Moreover, during the course of time necessary for the cure of the abscess, the contracted lung becomes coated with plastic lymph and young connective tissue, which not only tends to contract the lung further, but, later on, when the abscess cavity has healed and the external opening has closed and the contained air in the old abscess cavity has been partially absorbed by the bodily fluids, leaving a partial vacuum, as it were, the lung being bound down by lymph and connective tissue is unable to expand and fill the rarified space. This causes displacement of the viscera and sinking in of the chest wall to obliterate the space. The deformity caused by this

may demand a thoracoplasty, which, most likely, has already been called for to coapt the chest wall to the collapsed lung, in order to cure the abscess. The rational way it would then seem to treat empyema, so that thoracoplastic operations would not be required, would be to maintain throughout the treatment the expansion of the lung and at the same time effect continuous drainage. The ac-

companying cuts show an apparatus that I have devised, which has this for its object. It consists of a metallic or glass box "1" of about 300 c.c. capacity, with top and bottom screw-threaded perforations, a perforated, nippled screw-top "2," a perforated screw body flange "3," and a section of pure bandage rubber of suitable size "4." The application of the instrument to the body is effected by fitting the hole in the center



of the rubber the screw of the body flange and then screwing the flange to the drainage box, making an airtight junction between the rubber and the instrument. The under surface of the rubber is then cleaned and roughened with emery cloth and a coat of rubber cement is applied and allowed to dry, the corresponding surface of the body over which the rubber is to be applied is also cleaned, coated with cement and allowed to dry. On application of the rubber to the body it will be found to adhere very tightly, making an airtight junction between the instrument and the body. If now the top is screwed on and connected with an exhaust pump by means of a rubber tube fitted over the perforated nipple, the air partially exhausted and the rubber tube tied, the instrument can be worn with comfort and will maintain a partial vacuum for an indefinite period. The diameter of the hole in the body flange is 1⅝ inches and the incision for the resection of the rib would best not exceed it, in order that the wound may be at all times accessible for inspection. With the resection made, the apparatus attached, the drainage tube would lead into the cavity of the box, which is filled with gauze, the top screwed on and the air exhausted, the operation would be complete. By unscrewing the top the dressings may be removed as often as necessary. The amount of suction to which a diseased lung can safely be subjected is as yet undetermined. The amount which would overcome the elasticity of a normal lung would be very small, 10 to 20 mm. Hg. The amount of rarification in the instrument could be approximated by having the nipple tube collapsible at a given atmosphere. The theoretical advantages of this method of treatment, besides those given, would be, that the expanding lung would assist in the drainage of the pus, the lung perform its normal function and the negative pressure between the pleura be re-established and maintain its aspirating effect on the venous circulation. The apparatus would of course be useless if the pleural abscess communicated with a bronchus. Its use would best be suited to early cases, and by its preventing the collapse of the lung the usual hesitancy about making an opening into the pleural cavity would be overcome. I regret that I have not had an opportunity to put this method to a practical test, and publish this description with the hope that some who may be interested, and deem it practicable, may give it a trial.

## THE ADVISABILITY OF A MORE DEFINITE COURSE OF INSTRUCTION IN PHYSICS IN THE MEDICAL CURRICULUM.*†

BY ALLEN J. SMITH, M.D.,
OF GALVESTON, TEXAS.

I WOULD preface the matter of argument by calling attention to a mental attitude very common in medical students, the aptness to regard the mere gaining of a diploma as the summum bonum of a course of study—a habit of thought which unfortunately is capable of being carried forward into the medical practice of the physician in viewing the possession of a diploma as justification of whatever lack of skill and practical inefficiency may be exhibited in his professional life. There are of course many exceptions to the unfortunate truth of such an assertion; but in the minds of

*From Laboratory of Pathology, Medical Department of University of Texas, 1903, No. 4.

†Annual Address of Chairman before Section of Pathology, Texas State Medical Association, San Antonio, Texas, 1903.

those accustomed to deal with large numbers of medical students the reality, however it may be regarded, of the first part of this proposition can scarcely fail of recognition; and it needs no long search in the great body of our profession to find ample evidence of the second. In fact there lie at the bottom of these mistaken purposes and opinions so much of common human nature, so many of the temptations of an artificial strenuosity of life which has never more than now prevailed in our country, that indeed it is a matter for wonder that such faults of preparation and evasions of responsibility in action are not more numerous than they really seem.

Granted the truth of such statements it naturally follows that in the mental processes of individuals of such type there should be exhibited the equally faulty wish and effort to obtain the desired diploma and such license as it may afford at the least possible expenditure of energy, time and other valuable consideration; and in whatever feature of preparation for medical practice there appears opportunity for evasion of difficulty, of conservation of mental effort and temporal and financial convenience, in that phase of the educational course of the individual such evasions are likely to be practised. Naturally, too, in those subjects of the curriculum which do not on their face bear evidence of their immediate relation to future professional requirements are likely to be concentrated these attempts at evasion; and thus it comes to the untrained, unadvised or ill-advised student of medicine that he should regard all his studies and exercises dealing with the so-called preliminary branches of medical training as unproductive, relatively valueless and undesirable, and justly to be neglected when opportunity obtains.

Of the branches of the medical curriculum or preparatory to it which in the experience of the writer are regarded by this type of student as veritable bug-bears, *physics*, *chemistry* and *general biology* probably occupy the first rank, and probably among themselves stand in the order given. That there are reasons for the widely prevalent views of this sort among our classes is not of course to be doubted; but it is not my aim to recognize and discuss such reasons. Moreover, I do not wish to attempt to show reason for insistence by medical instructors upon thoroughness of study in all of these branches of science by our classes. Both chemistry and biology seem in a fair state to prove to even the most unthinking their absolute necessity to the really competent physician; and in fact need neither defence nor laudation. Chemistry at one time shared with anatomy in its all-pervading dignity in the medical curriculum, but rather from its relations with compounding of remedial agents than with either physiology or pathology. With the division of labor between physician and pharmaceutical chemist the older value of chemistry grew less and less in the appreciation of the first; and, eventually, had it not been for its ancient predominance and the value of occasional applications in symptomatology (especially of the urinary diseases) it would doubtless, with botany, have been entirely relegated to the pharmaceutical curriculum as non-important to the medical man. But here as in all human habits of thought there is a pendulum swing, now carrying back to its old prestige the study of chemistry, changed, it is true, in the type of its presentation and application, but each year recognized more and more in the form of physiological and pathological chemistry as one of the undeniable and main supports of our best medical knowledge. It is safe to say that within another generation physicians who are not also competent chemists will occupy just as little advanced position in the profession as do those now who are incompetent microscopists. The widespread interest in nature studies, reaching well down into the lower grades of our common schools, is sufficient assurance of the final position which general biology, at least as a preparatory branch, must bear for those who look forward to a life in medicine.

It is no great wonder that ancient and medieval physicians were not also physicists as they were chemists, when we recall the crude ideas and limitations of the general subject until comparatively modern times—the really modern establishment of such basic ideas as the true relation of the earth in the solar system, the rotundity of the earth, the law of gravitation, the control of electricity, the mechanics of steam, the conservation and transformation of energy, the vibratory theory of force and a host of cognate matters, to say nothing of the discovery of the circulation of the blood, the cellular structure of the body and the cellular theory of disease.

In the manifold applications of the principles of physics in modern everyday human life men of a score of specialized professions are employed; yet nothing of the intricacy of construction and specialization of parts, of coordination of each to the whole, often inferred rather than clearly seen, in the mechanism and function of the animal body can be realized in the entire group of the engineering professions. There is not a single branch of the medical course of study, moreover, which does not in recognizable way and degree call forth, directly or by analogy, the fixed principles of physics as clearly as in any engineering problem. The architectural ingenuity of man is barely comparable, if at all, to that shown in the adaptation of material for strength in the construction of bone, in the distribution and limitation of strain in the human skeleton; the principles of hydrostatics and of hydrodynamics with a system of compensations witnessed in the circulations of the body are applied with more intricacy and exactness than seen in the highest engineering accomplishments in connection with any of the waterways of the globe; the development and coordination of gross and minute movements of the body and its parts exhibit a desideratum for mechanical engineers to be envied but not to be attained; the production and maintenance in uniformity of the body temperature in all the varying conditions of

the body itself and its external relations in comparison with our best artificial means of heat production and regulation are as more than the work of the master to the work of the child: the complexity of the factors of physical and chemical processes operative in secretion and excretion renders the actual method almost a sealed book to the physiologist, but no man's machine is inscrutable to his fellows; the simplicity, convenience and effectiveness of the ocular and aural apparatus render our eyes and ears models to be approached but not attained by the ingenuity and skill of human inventors and mechanics; while the vast system of nervous paths and centers of the animal body may have an analogy in the most complex electric arrangements of men, the whole world of electric systems compacted in one mass can scarcely rival the delicacy, multiplicity and infinite accomplishments of the nervous apparatus of one human body.

That a branch of science having such elaborate relations with the animal body in health and in disease should find little and often no definite representation in the medical curriculum is from the first serious thought in itself marvelous. Perhaps the complexity of its bearings in medicine and the profundity of its relations to life phenomena stand as a first excuse for this most significant failure. Let this be so; it is no argument. Even Alexander's little world was not conquered in a day. No matter the magnitude of the whole, each part apprehended is a gain to human knowledge and somewhere has its practical application; part by part, every portion fixed upon the student's mind makes of him one better prepared to work out further problems for himself and for the rest of us. Nor am I unaware of the fact that these principles are here and there at the present time being given in one or other of the existing branches of medical study; but a part here and another there are by no means the same as a careful and definite résumé of the science and its scope of application to our needs; and further, those branches now working out these problems, as from time to time needed in elucidation of their own difficulties, are doing preparatory work, from which there is every reason to excuse them if we would wish them their fullest development in a speedier time. The ophthalmologist goes over a course before his class explanatory of the physics of light and lenses; the microscopist prefaces his instruction by a somewhat similar outline; the aurist discusses the vibrations of air and solids in the development and transmission of sound; the physiologist, the diffusion of gases, the laws of osmosis, questions of hydrostatics and hydrodynamics and practically every other subject pertaining to the branch in the explanation of a great number of instruments of precision and in elucidating that which is known and conjectured as to the various bodily functions; the obstetrician, the resultants of forces applied variously, successively and coordinately in directing and accomplishing the birth of the child—in short, each instructor takes up before his class some part or parts of a subject of fundamental importance to all and deserving an individual and dignified position in the scheme of instruction; and each loses just so much of his time and opportunities to press a little further toward his assigned object in the general plan.

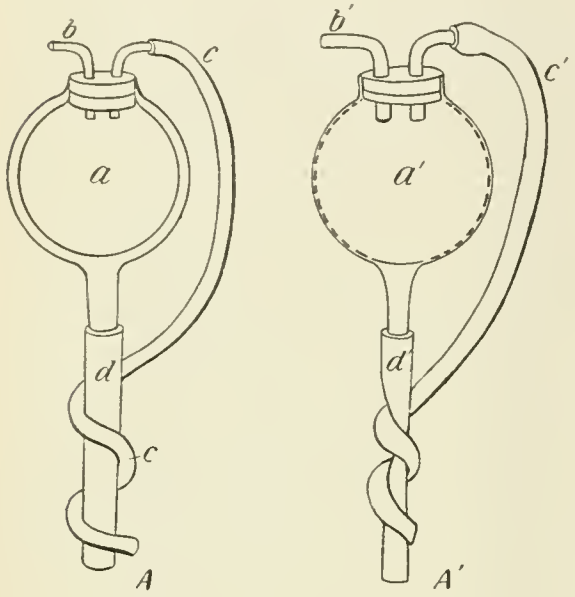
What would I make of physics in the medical curriculum? To the writer's mind the branch has a direct and particular phase of application which is spoken of as *medical physics*. For the student who has had no training in the subject when admitted to the medical school I would insist upon a course of lectures or text-book study with actual demonstration covering the general principles, and for all students laboratory exercises designed to familiarize them with the principles and actual manipulation of the various instruments used in experimental and in practical medicine, and to illustrate by experiment and attempts to mechanically reproduce outside the body by simple models such phases of nature's operations as may thus be copied. The latter part of the scheme, the distinctively medical physics, should be further elaborated according to the wish and ability of the instructor, by lecture or other mode of explanation, in indicating the multiplicity of factors and their mutual relations in the accomplishment of bodily functions, with immediate and direct reference to the influence of modification or loss of any factor toward the development of disease and its symptoms.

The matter of the construction and mode of handling of the various instruments used in experimental and practical medicine needs no explanation or illustration of its value to the student; and the release of the instructor from the necessity of discussing fundamental principles involved in his branch will doubtless be accepted as affording more chance for increased attention to and development of the particular features of his special subject. Dealing with those students who have attained the general ideas and a fair technic, the physiologist, the pathologist, and particularly the clinical physician and surgeon or obstetrician have fair field for presenting the final problems of their branches, the ultimate objects of instruction.

The student is taught that glandular secretion or excretion is dependent on the presence in the gland of more or less freely circulating blood as the source of the particular substances elaborated by the gland. He witnesses *a case of acute renal suppression* in the hospital ward and later at the autopsy meets with a deeply congested, red and swollen kidney. Will it help his appreciation of the development of the symptom if his thoughts be directed along some such line as follows? Setting aside for the time but in no way denying the importance of selective cellular activity, the mechanical forces and methods involved in urinary excretion are brought forward in greater prominence. The structure of the kidney speaks for filtration as at least one factor in renal activity, filtration of the fluid and more or less of the urinary salines from the blood. For the example in hand it is immaterial what further action the epithelium of

the convoluted tubules may accomplish. One may well compare the renal unit (the Malpighian tuft and its enveloping capsule and the tube leading therefrom) to a separator funnel lined with a permeable membrane and fitted with a compressible discharge tube. My meaning may, perhaps,

Fig. 1.



be more readily apprehended by reference to the diagram (Fig. 1, A) in which is represented an ordinary separating funnel, within which separated by an appreciable space from the inner surface of the funnel is fitted a permeable and expansile membranous sac (a) provided with an entrance tube (b) and exit tube (c) both of the same expansile type as the sac itself, and the exit tube (c) coiled about the compressible discharge tube (d) of the funnel. In a rude way this follows the type of the coiled capillary tuft within Bowman's capsule and the arrangement of its emergent capillary about the convoluted tubule of the kidney. Presuming that the pressure of the fluid within the membranous sac in the funnel (capillary tuft within Bowman's capsule in the kidney) is positive, but insufficient to stretch the sac to close adaptation to the wall of the funnel, the contained fluid will escape through every part of the membrane into the space between the sac and the funnel; and if that pressure be lowered the filtration of fluid will be diminished in rate. On the other hand (Fig. 1, A') if the pressure within the sac is increased (increase of vascular tension in the renal vessels, as in marked sudden congestion) it follows that the sac must expand to become closely applied to the wall of the funnel (the tuft to the wall of Bowman's capsule); whence it is clear that there is opposition to the escape of fluid from the sac save at the limited surface opposite the opening of the discharge tube of the funnel (the beginning of the proximal convoluted tubule of the kidney). It is to be realized that increased pressure within the sac must be carried forward along its emerging tube (c'), leading to the distention of the latter (providing the same difficulties of discharge as in the tortuous renal capillaries and veins), in this connection the particular feature of its expansion referring to its encirclement of the discharge tube of the funnel (the plexus of emerging capillaries about the convoluted tubules and the general capillary distention within the renal mass). If room for such distention is not given save at the expense of the caliber of the encircled discharge tube (as is the case in the kidney from the pressure of the general renal tissue and the resistent renal capsule) there must result narrowing or possibly closure of the discharge tube (d'), affording another mechanical factor in inhibiting whatever tendency toward filtration may continue in the funnel above; and if the pressure be sufficient through these two obstructions, one may readily infer total suppression of the filtration process. The walls of the capillaries of the Malpighian tuft are by no means entirely comparable to ordinary porous filtration membranes, but in the relation here proposed are at least analogous and in illustration of the mechanical influences named will easily bear the comparison; and silence concerning any part played by the renal epithelium in no wise impairs the illustration. Nor is it difficult to fix in the same bit of apparatus the ideas of the student as to the relation of urinary suppression and hematuria in such cases of renal stagnation from acute congestion.

Another striking example from pathology suggested by the same line of thought concerns *the explanation of the posture assumed by the patient with broken cardiac compensation* and approaching his end. It is invariable that as the heart fails the individual finds himself little by little forsaking his natural low recumbent posture at rest, seeking a higher and higher pillow, and as death approaches finding comfort only in a sitting posture with the limbs more or less elevated; and invariably change from this position to a lower or higher (more erect) attitude calls forth evidences of special cardiac effort. There are here, of course, as in most cases, a number of factors to be considered for the full explanation of the whole symptom picture; but of these that of the influence of gravity in distribution of the blood is the element of variation to which mainly must be attributed the symptoms in question. One should realize here that in the erect or sitting posture the column of blood in the aorta and its branches beyond the turn of the aortic arch must by its weight naturally produce no immaterial tendency toward keeping up the usual downward current (other factors of aid and resistence being disregarded for the time for the sake of the argument); while in the recumbent position the distribution of the blood over the whole body is practically the result of the propulsive force of the heart and vessel walls alone. The difference in cardiac labor in these two postures may be roughly stated as the

difference in lifting the column of blood from the left ventricle to the turn of the aortic arch and to the head in the first instance and the lateral propulsion of the whole arterial blood mass in the second. Or, to use a homely simile, it is comparable to throwing a ton of coals, shovelful by shovelful, over a low fence and allowing it to fall fifty feet in a vertical direction in one case, and, in the second instance, to the labor of transporting the same coals, shovelful by shovelful, across a level space for fifty feet and depositing it in a new heap. With such a view it is easily realizable that there is more labor demanded of the heart with the body adjusted in recumbent position than in either the erect or in the sitting posture, and that when the circulation is from many influences already weak and feeble, the added strain upon its walls may well call out marked evidences of its exertions. The sitting posture is assumed rather than the upright in such an instance for easily stated reasons, namely, the usual general muscular enfeeblement of the individual and (in the absence in either position of chance for free muscular and respiratory aid in venous return) the less labor of lifting the venous column of blood through the shorter vertical from the feet to the right heart when the individual is sitting than when standing. This too should explain the common tendency in such patients to keep the limbs moderately elevated when sitting, such elevation being insufficient to occasion much difference in the gravitation of the column of arterial blood but making an important difference in favor of more easy venous return from the limbs (the difference of height of the lower pelvic level and the floor).

These examples of the type of questions to be presented to the student in medical physics are crudely and but incompletely drawn; but they serve the purpose of illustration here desired and indicate the objective aim in urging the adoption of a definite course in the subject. They are both well suited to actual laboratory demonstration but not more than a host of other possible instances. In fact in the arrangement of a course it must be a matter of selection from the great number of examples possible; and the fullest scheme could not possibly deal with more than types, leaving the individual application to the intelligence and resources of the student for determination. It could not do more than attempt to inculcate a habit of thought along these lines, aroused by witnessing typical illustrations; and in the end this is one of the real purposes of every education, the establishment of a method of observation and of mental reflection and application of principles to the clinical problem of the physician. Beyond this the crowded condition of the curriculum would give but little justification for fuller work.

This matter of urging the adoption of a definite system of instruction in medical physics applies particularly to our American medical schools. For a decade or more in Great Britain it has come to be a required study for those applying for the ordinary qualifications; but in the university courses in medicine and surgery it was demanded for a much longer time. Much the same may be said of the continental universities as for those of the British. In our own country a demand for a certain amount of knowledge of elementary physics as an entrance requirement is common to all the schools holding membership in the American Medical College Association as well as to a number outside this organization. For the most part this requirement is worth nothing or very little better; in some instances the branch is but an elective in these requirements. In comparatively few college catalogues is the amount fixed at any really important grade. Inspection of catalogues shows, too, that in but a very small minority of our schools is there provided any additional work in the medical aspects of the subject; and of these few it is not at all sure in some but that the physics taught is absolutely elementary and rather introductory to chemistry, with which it is usually associated, than an applied medical physics. There are a very small number of American schools in which the catalogues indicate a really commensurate and suitable presentation of the branch, and this number by no means includes all the schools of the highest reputation in the land. Nor does there occur to the writer, in examining the prospectuses of the year or from personal knowledge or information obtainable, that there is any real tendency to remedy what after serious thought he has come to look upon as an unjustifiable negligence.

I confess to a twofold object in this sketchy presentation of what I fear is not a popular subject. The first is of course that of attracting the interest of the members of the association to the importance of medical physics in itself and to its rather common disregard in most of the American schools of our profession; but I have more directly in mind the intimate relations of this Association to the State and its medical school. In the Medical Department of the University of Texas no preliminary knowledge of physics is asked of the student about to matriculate. From early in its history the professor of chemistry, Dr. S. M. Morris, has devoted in the first half of the freshman year two hours weekly to a lecture and demonstrative course in the subject with special reference to its bearings in medical study, but has been unable, principally from lack of space and appropriate equipment to develop the actual and needed laboratory course above suggested. It is unlikely that it will be possible for years to come to demand such a degree of preliminary knowledge of the subject that it might be dropped from the course, were this desirable; since entrance demands from professional schools must in distinct degree depend on as well as lead popular education. It is toward the establishment of a fuller, more practical and more directly medical course in physics in our home school that, in closing, I wish to leave your thoughts, in which wish I know the ideas of my colleagues in the faculty of the school and my own are in accord;

and for which I am in position to know that the Regents of the University, advocates of progress wherever and whenever possible, are powerless, as in many other features of the school where advances and expansions are desirable, solely because of financial disability. I would not ask of you any concerted action in any of these matters, since such action is apt to be transient in its influence and of less value than individual effort; but I would ask of those of you to whom this paper may have appealed as reasonable to use your personal powers and influences to create in our State a popular interest in and willingness for the school to advance not only in the limited lines indicated in this paper but in all lines leading to the highest attainable efficiency.

## MENTAL THERAPEUTICS IN MEDICINE.*

BY J. M. AIKIN, M.D.,
OF OMAHA, NEB.

Those unsatisfactory cases referred to the domain of neurology and psychiatry by the physician and surgeon constitute a very formidable array of facts we meet and should solve. Admitting our inability to benefit these cases is against the spirit of progress in the medical profession. Our failures are, I believe, more chargeable to the profession than to the patients. This statement is no injustice to our profession, that has studied the body as a physical organism, in the battle against chemical and parasitic disease. Indeed, so interesting, instructive and progressive have these material investigations proved that many simple physiologic facts, clearly within the realm of the mental, are quite forgotten in our therapeutics.

The revelations of bacteriology and microscopy have so engrossed our attention that the action of mind on body and body on mind is almost a lost factor in our art. The interrelation between the physical and mental organism of the individual within physiological limits is common knowledge; when pathological relations exist, medical knowledge is sought.

The everyday effects of the mind on the body in the processes of digestion and assimilation, secretion and excretion, are so obvious they are overlooked in our search for rare and striking effects of mind on body. Since the common effects constitute a decided majority, it will lend us greater assistance if we reckon more closely with them, than with the uncommon, in practising the healing art. We see the physical organism out of balance and proceed to treat our patients as machines to be repaired by physical and chemical remedies alone. I believe it is a fact that the success attending any physician's practice is due in greater measure to the mental impress he stamps upon his patients than to the drugs he gives. Or stating it differently, the confidence he elicits by the patient's faith in his ability to effect a cure will go farther toward relieving the ailment than would the physical and chemical treatment without confidence in the doctor. Witness the testimonials of patients who frankly tell you your medicines always benefit them, when the same drugs given by another doctor are not only futile but often aggravate the ailment. Calling this imagination with the injunction that the patient take an introspective view of self and adjust his mental organism is admitting the mental factor while shifting our responsibility for treatment to him.

The framework called the body organized with bone, muscle, and nerve cells is but a mass of degenerating tissue when out of touch with mind, the constituents of which are perception, intellect, will and emotion. We know the mental factor is dynamic in producing disease. We know, too, the same force operates favorably in producing health. The blue pill and Epsom salts are noble, obvious, palpable, physical and chemical remedies. Force and boldness are intangible remedies applicable and operative in the mental realm. Why do medical men leave the exercise of force and boldness in therapeutics to the charlatan? Intelligent mental force and boldness in exploring unseen regions in the body has enabled surgery to perform many cures where exact conditions were wholly unknown before the remedy was applied. Do practitioners of rational medicine know less of physiology and pathology in the domain of the mental than the long-haired quack? Surely courage, dignity and the indelible impressiveness of a strong personality are nowhere more pronounced than in our profession. Why then is mental therapeutics shunned by a large proportion of our profession? Many reasons may be assigned, but two are especially obvious: (1) The period of intelligent practice of medicine is but an infant compared to the many years that witchcraft and superstition dominated the healing art. The progressive thinkers were a helpless minority until recent years. Gradually intelligent thought directing physical and chemical remedies in action on material structures produced effects which appealed to perception as beneficial to the individual. (2) Exploration in the materialistic realm presenting as it does so many tangible facts, has detracted from inquiry into the intangible domain of mind. We are, however, daily observing facts which show conclusively that the mind is a dynamic reality. Neglect of the mental did not lessen its activities, which for want of intelligent direction became the field of operation for the masses of illiterate who could perceive effects, without reasoning to their cause. It is only in recent years that psychology has been intelligently studied in its application to unnatural bodily states. Gradually we are learning to direct these mental forces to helpful influences on the body. The effects produced have been received with incredulity, yes, even ridiculed more rigorously than Jenner's vaccination, which our homeopathic friends use without perceiving its modus operandi.

The believers in rational, mental therapeutics

*Read before the Nebraska State Medical Society at Lincoln, Neb., May 28, 29, 30, 1903.

are increasing so rapidly that only the minority are pessimists concerning its utility in practising the healing art. Not many years since when brain surgery was proposed the majority passed adverse judgment on present possibilities. It is not because our profession is wanting in men capable of utilizing mental therapeutics, but because our schools have failed to properly instruct students concerning physiology and pathology in the psychic realm. The physician who now enters practice in any department of medicine without a working knowledge of psychology is heavily handicapped. Specialists who study the whole man, though directly practising but one department, are the men who see and utilize the force of mind in medicine.

If wresting the physical and chemical treatment of disease from the realm of superstition to its present plane of rational medicine has been difficult, the rescue of mental therapeutics from Mesmerism, hypnotism, Dowieism, Christian science, plus the multitude of "pathies," each of which is but an excrescence on rational medicine, is harder. It is more difficult because it presents something active that cannot be weighed nor measured. According to Ladd the assumption that the mind is a real being, which can be acted upon by the brain, and which can act on the body through the brain, is the only one compatible with all the facts of experience. This makes the body and mind each governed by laws in its own realm, yet inseparable and interacting during life. Cases illustrating this truth are so familiar to all I cite only one:

Miss A., aged thirty-eight years, was admitted to the Methodist Hospital, Omaha, November, 1901, where I called to see her. For twenty years her mode of locomotion had been either in a wheel-chair or carriage. From birth to her eighteenth year her health had been excellent. In her eighteenth year she had an attack of fever, the true character of which we were unable to learn. She said her physician called it malaria. This fever lasted three or four weeks. When convalescent she attempted to walk, only to discover her lower extremities too weak to support her weight. No history of any sensory disorder. No deformities. Present condition: Muscles of lower extremities flaccid and but slightly wasted. Reflexes and sphincters normal. Tongue coated. Intestinal fermentation, with persistent constipation. Repeated examinations convinced me she was an invalid from long introspection. Too early attempted use of her legs was succeeded by a prolonged non-use beyond the period when they would have sustained her weight with moderate exercise. If she would walk again she must relearn the process. This she did in a few days. In four weeks she walked a mile each day, and in three months had the use of her entire body. The material therapeutics I used was Sod. Phos. daily for several weeks. The mental therapeutics I employed consisted in supplying her with conditions suggesting the use of her legs, removing all evidence of physical help by others, giving positive assurance that her spine was not diseased, and that we all knew she could walk a specified distance. This mental medicine stimulated her to effort, and the task was soon accomplished. Her courage was now in the ascendency and restraint from too arduous exercise, was necessary. Without consulting her judgment of what she could or could not do, I mapped out as on a checker board a graded scale of exercises for her daily use. I specifically indicated her diet and the hours when she should eat, sleep and exercise. She told me everybody, doctors included, said her spine was diseased, that she could not walk, and she, believing this, suited her actions to the dictations of her mind. I never interrogated a more "unwilling witness." She had been thoroughly drilled in answering questions intended to establish it as a fact, that her spine was diseased. On cross-examination her ability in evading self-contradiction was remarkable. This extreme case illustrates what we all see in lesser degree in our daily practice. Experience teaches that the laws governing the bodily functions originate in the realm of the mental. With this fact existing, we may only rise to the possibilities of our profession when we cultivate an acquaintance in the domain of mind, commensurate with our understanding of the physical body.

---

## USES AND LIMITS OF NON-PHYSICAL THERAPY.

BY SMITH BAKER, M.D.,
OF UTICA, N. Y.

No discussion of the uses and limits of non-physical therapy can reach tenable conclusions without first defining what is meant by the term.

When this attempt is made one becomes conscious that the data for such a definition are largely wanting. The conception, non-physical therapy, is yet a mist of vague generalizations from which it is difficult, if not impossible, to draw forth an image clear or very promising.

From what one can learn, non-physical therapy seems to include not only the use of subjective forces, whatever these may be, but also of the various media through which these supposed forces are manifested. Thus the "mental healer" not only thinks what he desires to accomplish, but seeks by certain physical means, both ordinary and extraordinary, to convey his thought to the comprehension of his client. Even where so-called "telepathy" is assumed, it is supposed that some subtle bridge or other serves to convey the molecular agitation of the influencing brain to the ready-to-be influenced brain of the recipient. At least this is what I glean, not so much from what is published as from methods really used in special instances. And so with the "prayer-curist," the "faith-healer," the "scientist," and the like. The practitioner himself not only prays either silently or audibly, or does something objectively patent, but also requires an actively responsive subsidence of all opposition and doubt on the part of his subject, just as there must be more or less

acquiescence when hypnotism is exercised. In either case there is more or less use of physical means through voice, vision, touch and the like; which means are quite as obviously necessary as is the subjective power behind them. Even Dr. Riviere, in his very recent paper before the International Medical Congress, makes his conception of psychotherapy to include the uses of heat, light, and electricity; while a recent caller has astonished me by affirming that the newly discovered gaseous elements, argon and helium, are the medium through which all such influences are transmitted. We see, therefore, that in a definition of non-physical therapy which shall strictly conform to facts only, we must admit at least a modicum of physical elements, in addition to whatever non-physical ones we may choose to include.

But this is not what the authoritative votaries of non-physical therapy claim. They usually affirm that the influence is purely immaterial; is, in fact, an influence of "pure mind," or "pure soul," upon some other one. Sometimes this is said to be embodied, but in some supraphysical way, as, for instance, in the cures of so-called "spiritualists"; yet, in the end, "pure mind" or "pure being" is held to be the real fountain and stream of all the non-physical therapy, which, to them, is worth considering.

This attempt to define non-physical therapy brings us at once to an important conclusion, namely, that, before its uses can be determined, there must be more accurate investigation of all these matters, and more credible records of both subject-matter and results, than are now to be found, and this, in spite of the labors of those who have already attempted to place them in a truly scientific order. Probably there is nothing in all the broad realm of functional neuro-psychoses that is so universally evident at the present time, as the part played, either for good or ill, by non-physical therapy. Almost every case, at some time or other, goes through some phase of it, and quite as often as otherwise to no good whatever. On the other hand, there really are instances of neurasthenia, and hysteria, and chronic invalidism, aboulia and dependence, which are markedly helped, and this more or less permanently, and too, after various futile exhibitions of material appliances and remedies. That there is something which our gross and even our fine pathologies, and all our medicinal and medical remedies do not yet explain and reach, is gradually being defined, by many, yet crude, practitioners in these various fields. What that something is, and how to find out about it and legitimately to make use of it, remains yet to be seen.

This will not, cannot be, however, until several difficulties are themselves better defined:

1. There must be a clearer notion of the difference between initiative and cure. To start a person on the road to recovery may by no means assure his traveling it successfully to the end. Yet this is just what the non-physical curist assumes more frequently than otherwise. Thus the wife of a physician of my acquaintance could not sleep. No kind of legitimate medication seemed to have the desired effect. The doctor heard of an institution where such things were cured by so-called "therapeutic suggestion," and sent his wife there. She was promptly assured that she could be cured, and very soon she was cured, that is, apparently. Encouraged by this, the doctor himself went to the institution for instruction in the art, which he seems to have pursued thoroughly. Since which time, however, he is obliged to treat his wife rather regularly in order to keep up the sleep habit, first suggestively induced. As an initiative, the suggestive treatment was a success. As a cure, not so, any more than the ordinary hypnotics would have been. Cure, in any given case, may stand for very different results; as, for instance, simply to restore to the former degree of health; or, only to a partial degree of health; or, only to an abiding hope that eventually health will be attained; or, to the stage of a mere temporary relief. In either case, both the popular and the professional idea of cure seems to be but vaguely differentiated; yet this constitutes a real limit to the uses of non-physical therapy, which seems to be rather deeply fixed. Cure, in any comprehensive sense, should include both the beginning and the end of the disease cared for.

2. Another difficulty, a profound and far-reaching one, which must be taken critically in hand before the uses of non-physical therapy can be determined, is the professional apathy, fear, and taboo with which the whole subject is so commonly regarded. We naturally shrink from the uncanny, to say nothing of the ignorant conceit and assertive presumption which so generally deal with it. "There is nothing in it," easily satisfies, and allows us to think that if we stick to physical methods closely enough, we have done our whole duty. There is also the allied fear that we shall simply make ourselves ridiculous, and, in the end, accomplish little or nothing worthy of our pains. Altogether, it is truly enough a subject for taboo, either tacit or actual; but, as such, is involved in a difficulty which must be overcome before headway in investigation can be made or definite indications or uses be determined.

3. Other difficulties are the essential ones which possibly may never be overcome. Especially is the impossibility of analyzing such concepts as "mind," "spirit," "faith" and the like forbiddingly important; so much so that one hesitates to attempt anything bordering upon the subject. Yet we have only to think that it is precisely the same case with heat, light, electricity, chemism and the like to see how interferingly fallacious such a feeling is. Here no one thinks of trying to resolve the concept into simpler terms. Heat is heat, light, light, and so on. And so on, too, mind is mind and nothing more in the last analysis is possible. Yet, as in the case of so-called physical agents there has been no end and there seems to be no end possible to the extent to which investigation and knowledge of their manifestations may be carried, so let us hold that

even though we cannot define mind, soul, etc., we can proceed to study their manifestations with a thoroughness which has never yet been given, and with at least some prospect of encouraging success. So long, however, as we wilt and refrain under the spell of philosophical nescience we will most certainly make no headway.

4. This leads to the important question, Is there actual need of special training for this kind of investigation? Much can be said, undoubtedly, concerning the worth of the work of all who have heretofore carefully worked along these and similar lines; but one cannot refrain from believing that their results would eventually have been much more convincing, had the investigators and reporters, to a greater number, been practising neurologists and psychiatrists, especially such as may have been rightly facultied, and qualified in special ways for such an undertaking. The trouble, thus far, has been that in too many instances the materialist has seen only material sequences in the human world: while the immaterialist or, technically, the idealist has seen similarly that everything is derived from and hinges upon immaterial foundations only. What is needed, is an all-round observer with keen eyes for mind matters and for body matters and for related affairs, all in one vision. At any rate it is increasingly evident that until the matter of non-physical therapy is taken in hand by those especially qualified to be capable of this vision, it will be practically impossible definitely to determine what the field and limits of non-physical therapy may really be.

But given accurate data and definite conclusions, it remains to ask, Is non-physical therapy properly a remedial desideratum? To which the answer may be given variously, according to predilection and experience.

Nothing that mankind becomes vitally interested in should be regarded as too trivial for investigation or use. The fact is, many of the so-called diseases themselves are, from certain points of view, rather more frivolous than otherwise, yet no one would deny their being legitimately the subjects of labored observation and much reflection. If this matter of non-physical therapy seems trifling or frivolous, we must remember that both to the sufferer and his healer it often seems to be of an importance much too serious for ridicule or neglect. The rather, both the practitioner and his subject have equal need that there shall be skilled elucidation of that which at present is so speculative, if not fraudulent. Either there is something in these matters worth while or there is not. Practically we cannot escape certain problems which definite instances present in every clinic. Thus, a cultured woman, aged thirty-five years, married, residing in one of the larger cities, having an acquired neurasthenia of long progress and standing, had been under the care of a leading practitioner who gave her electricity, tonics, baths, rest, massage, etc., assiduously, but yet without much benefit. She now declares that, in some way or other, she absolutely must have relief from her alternating mental and nervous irritability and weakness and apathy. She adds that an acquaintance, who seemingly was like her, has meanwhile been under the care of some sort of faith healer and has been cured. Cannot she, too, be benefited? If not regularly, then in some such manner, and so forth.

Now, such typical problems demand solution repeatedly, both in our own practice and in those of our confrères. Tired and disgusted with the ordinary physico-remedial measures, such people logically ask, if some sort of non-physical therapy is not in order. To which, who of us is now prepared authoritatively to say. Yet, says Dr. S. Weir Mitchell: "If he does not intellectually respect the complex matters of soul, mind and body and their interdependence, he is unfit for the higher seats in the temple of the god of medicine."

It seems to me, then, that inasmuch as medicine not only discusses the body and its functions and diseases, but also the mind and its peculiar aberrations and alienations, there is no impropriety whatever in admitting the legitimacy of the field of non-physical therapy, as one for research and possibly for practice. As a matter of fact, the study of non-physical phenomena, whether remedial or otherwise, is but a study of reflexes, and as truly this as is that of the knee-jerk, or the ankle-clonus, or the Argyle-Robertson sign. Only they are reflexes of a so-called higher and certainly much more complex and diffusive order, than these latter are. Possibly, it were worth while just now to put these on a par exactly with the simpler sensorimotor phenomena, and always to require their elucidation whenever the nature of the case demands. Practically, every case of disease has its more or less pronounced associated psychosis which often varies both the natural history of the physical ailment and the effect of the remedies prescribed. Moreover, it is a common belief that suggestion plays an important part in determining the ultimate uses of ordinary remedies. It would not be a very unwise step at least to attempt as never before to place all this on a par with other branches of medical science and practice.

Nor need we hesitate to do this because *a priori*, and even most probably *a posteriori* a generous use of the imagination will have to be made in the prosecution of the enquiry, as well as in the statement of final conclusions. The fact is, there has been and there must be all along, this very imaginary or subjective element in all our histology and pathology, even as there is in all the basal conceptions of the purest physics everywhere. When we think of it, such fundamental notions as the "nebular hypothesis," "evolution," "atomic theory," "neuro-psychical parallelism" and the like are simply figments of imagination, the pictures which the mind discloses as it attempts to comprehend the constitution and function of the universe. But this is considered to be perfectly legitimate: and especially so, since

the masterly essay of John Tyndall on "The Scientific Uses of the Imagination" was published. And so in all our conceptions of histology and pathology, materialize them as we will, there is yet included representative as well as presentative elements, and this to no impairment of their worth whatever; for we all know that they each and all stand, at best, as working hypotheses, to be modified, as future discoveries and thinking shall determine. So must it be in any and every attempt to study and relate the field of neuro-psychical therapy. Imagination will have to be used, and this generously. The only question is, Who shall be considered able to do it so that credence can be given to its conclusions?

In conclusion, then, we must note, that the irregular practitioner, either honest or dishonest, is gradually defining a field of non-physical therapy which sadly needs investigating with all the skill of the highest grade of endowment and training: also, that this cannot be done, except those who have the requisite preparation devote themselves to it persistently until the facts are ascertained. The ideal investigator in this field would seem to be one who, with a most thorough academic and professional education to begin with, shall then take post-graduate courses, not only in every practical field, but having likewise disclosed an aptitude and liking for psychological and psychiatral research, shall take special courses in these fields also. To such a one the way to satisfactory achievement is wide open, and certainly not crowded.

---

## THE SIGNIFICANCE OF ALBUMIN AND CASTS IN SURGICAL PATIENTS.*

BY JOHN C. MUNRO, M.D.,

OF BOSTON, MASS.;

SURGEON-IN-CHIEF CARNEY HOSPITAL, FORMERLY ASSISTANT VISITING SURGEON, BOSTON CITY HOSPITAL; INSTRUCTOR IN SURGERY, HARVARD MEDICAL SCHOOL.

The statement of a surgeon of considerable experience that he would not operate in the presence of albumin and casts, except in cases of great necessity, excited the writer's curiosity to investigate the prevalence of these indications of renal disturbance in recent surgical patients at the Boston City Hospital.

The report must be considered as barely more than preliminary in character. To carry out such an investigation to its full completion would mean years of observation of individual patients in large numbers, a task almost impossible when dealing with charity patients. If the statements of life insurance examiners be true that temporary albumin in the urine does increase the risk, even though to a slight degree, it must in the same way influence the later histories of our surgical patients. That it influences the immediate history, however, of patients suffering from surgical diseases is extremely doubtful.

Without doubt there is danger in operating upon a patient whose kidneys are incapable of sufficient elimination and where there are secondary organic changes. But because a patient exhibits a small amount of albumin, hyaline and fine granular casts, with renal cells, the conclusion should not be hastily made that he is not a fit subject for operation. Definite contra-indications in the way of deficient elimination, vascular degeneration or other organic changes must be present.

On the other hand, to avoid the mistake of being too casual, the presence of any renal danger signals should make one take heed lest he overlook concealed or unsuspected serious lesions.

Five hundred cases showing albumin and casts in the urine admitted within the last two or three years into the surgical wards have been roughly analyzed. Altogether 4,185 cases were considered. Of these, none that showed obvious renal degeneration or glycosuria has been included; nor have patients suffering from genito-urinary disease, burns, erysipelas or similar diseases been included. We found, first of all, that approximately a good 35 per cent. of all patients treated in the surgical wards showed signs of renal trouble. This is probably a fairly accurate proportion of surgical patients in whom we must expect to find albumin, casts, etc. Indeed, we believe this percentage is below rather than above what we should look for, because it is not rare to find a record made by the house officer of "negative urine" where an attached urine chart shows that albumin and casts have been found. In other words, the significance of small traces of albumin with or without casts may be of so little value in the average patient that the house officer dismisses the findings as of no importance, especially where the progress of the case has been uneventful.

Practically every form of injury and disease is included in the present 500 cases, the majority being of serious nature. At least 60 per cent. underwent operation. About 12 per cent. suffered from fracture. In this connection it is of interest to note that these patients, with few exceptions, were etherized, many for operations of length, yet there is nothing to indicate that any renal damage was inflicted by the anesthetic.

The urine examined was that which was passed soon after entrance to the ward. The accuracy of the examination varies more or less with the ever-changing house officer. Undoubtedly rare casts and cells were frequently overlooked in the pressure of work. The quantity of albumin varied from the slightest possible trace to one-eighth per cent. In 16 cases one-fourth per cent. was recorded; in some of these the quantity diminished later to a trace or disappeared entirely. In others, amyloid disease was probably present. Occasionally no albumin was found, although casts were recorded.

In about half of the 500 cases casts are definitely recorded, probably less than the actual proportion. Blood and pus occurred very often, especially in the urine of women. Fatty casts and blood casts were not infrequently noted, but apparently they bore no special significance. The

* Read at Meeting of American Surgical Association, Washington, May, 1903.

twenty-four hour quantity of urine was not included in the reports of any of these cases. Patients as a rule that required special attention in this regard were eliminated from the present inquiry, as there were suspicious or marked renal or genito-urinary lesions.

In brief, we were curious to determine how much apprehension we should feel when about to operate upon patients without obvious renal degeneration, passing plenty of urine of good specific gravity, in which a trace of albumin with casts is unexpectedly found.

To take up in detail certain points we found that about 10 per cent. of the cases occurred in children under fifteen years of age. This was a much larger proportion than was expected, and as only eight per cent. of all patients treated at the hospital are children under thirteen years of age it makes the proportion astonishingly large. Furthermore, we find that 44 per cent. of the cases were between the ages of sixteen and thirty-five years; the time of life when albumin, at least in non-surgical patients, is supposed to be comparatively rare. Between thirty-five and sixty years of age we find 36 per cent. of the patients and about 10 per cent. were over sixty. What the relative proportion of the various decades bears to the ages of the 4,185 patients was not determined, but in whatever way it is considered, the relative and actual number of children is higher than anticipated.

The cause of the albumin and casts is difficult to determine. Nearly a quarter of the patients over fifteen years of age entered the hospital for some form of traumatism, and presumably the renal trouble was present at the time of injury. It is fair to infer that the children were active and well at the time of the injury that brought them to the hospital. Possibly alcohol is a factor in the renal irritation, because it would seem to be almost the exception for an adult patient, male or female, not to use alcohol to some extent. Many are steady drinkers; some drink to excess. Whether this alone or the combination of alcohol, insufficient or improper food and hard work is enough to cause the requisite irritation it is difficult to say. It is certainly suggestive. Sepsis, unhygienic surroundings and improper clothing are probably factors in causing albuminuria in children. In a few cases, too few to be more than suggestive, the albumin and casts that were present in the first specimens of urine passed disappeared in subsequent specimens; sometimes after operation, sometimes in cases not operated upon. A number were found in septic cases (appendicitis, etc.), where the renal disturbance seemed due to the sepsis, subsiding as soon as drainage was established by operation. The effect of simple food, rest and warmth must be considered as well. It is quite possible in non-septic cases anxiously awaiting operation, that a temporary albuminuria may be caused by the mental disturbance in a way similar to that in which cardiac murmurs are not infrequently caused.

Of the 500 cases tabulated, 63 died. These will be considered later. In the remaining 437 patients, the natural query is whether convalescence was influenced in any way by the presence of albumin and casts. So far as could be told from a general review, without carefully analyzing each case in detail, convalescence seemed to be such as one would expect under the general circumstances; in other words, normal recoveries were as satisfactory as could be desired. Where there were complications or set backs, there was adequate explanation on grounds independent of any renal lesions.

In the 63 fatal cases, casts were absent or not seen in 30 per cent. Eight patients died from shock. Of these, one patient, seventy-two years of age, with advanced carcinoma of the breast, died almost immediately after a long operation. It is barely possible that a slight renal lesion had some influence on the result. Two died after operation for general peritonitis, one each from multiple injuries, operation for appendicitis with profound sepsis, typhoid perforation, hemorrhage following common duct operation, and septic pelvic abscesses; all potent causes of death without the slight effect from kidneys doubtfully damaged. There were 5 deaths from pneumonia, 3 from tuberculosis, 19 from general sepsis or severe peritonitis, where there could be no doubt as to the infection alone being a legitimate cause of death. In addition there were deaths from embolism, malignant disease, cardiac disease, skull fractures and pancreatitis, where the rôle of the urinary organs must have been insignificant. Of four cases in which death was ascribed to senility, one with cellulitis of the arm had one-quarter per cent. of albumin and casts, one with intestinal cancer had profuse diarrhea, one had a strangulated hernia, and the fourth died one month after a fracture of the femur, showing only the slightest possible trace of albumin, with hyaline and granular casts.

To glance at the record of the examination of the kidneys in 12 cases that came to autopsy, not included in the group just discussed, we find that one case of portal pylephlebitis showed fatty degeneration of the kidney, another similar case had normal kidneys, as did a patient dying of gastric carcinoma, sarcomatosis, rupture of the liver and compound fracture of the leg. Fatty degeneration was found in cases of general peritonitis and sepsis, and in a fractured pelvis with pulmonary embolism. A left pyonephrosis was found in a case of abscess of the liver. A chronic passive congestion in a case of osteomyelitis with pericarditis, and an amyloid kidney was found in a case of general peritonitis. With a possible exception of the patient dying after breast amputation and the old man dying with cellulitis of the arm it requires a long stretch of the imagination to give any weight to the urinary conditions in the fatal result of these 63 cases.

In conclusion we should expect evidence of renal irritation in over a third of the surgical patients found in a municipal hospital. The mere presence of a trace of albumin, with or without

hyaline and granular casts, unattended by other evidence of renal damage, should not influence the prognosis in surgical disease or operation. The presence, however, of albumin and casts should place us on the watch for other and more significant signs of organic degeneration which may prove serious obstacles to operation or satisfactory convalescence. Furthermore, albumin and casts alone are apparently no contra-indication to the administration of ether. The age at which we must expect albumin and casts in surgical patients is under thirty-five years in over half the cases. The proportion in young and otherwise healthy children is probably as great as in adults.

---

## LATER IMPRESSIONS OF THE "NON-HEREDITY OF ACQUIRED CHARACTERS."

BY LEWIS S. BLACKWELL, M.D.,
OF PERTH AMBOY, N. J.

In his review of an article on "Impressions of the Non-Heredity of Acquired Characters," that appeared in the Medical News of December 20, 1902, the author, Mr. Lawrence Irwell, a member of the Bar of Buffalo in a recent communication, apparently sweeps the field like a great cyclone by his legal acumen and scholarly attainment.

The valor of the medical profession seemingly demands a restitution of the proud structures that have been erected along the corridors of the centuries.

Having recovered from the shock, a disciple of Æsculapius essays the task of clearing away the débris occasioned by this forensic fulminator. His sophistry and the character of the arguments he advances furnish a suitable site on which to rebuild.

With the audacity with which Mr. Irwell attacks the medical authorities the writer cites in support of his position, one naturally would have supposed he would have introduced to the profession of medicine educators more renowned in therapeutic literature and less vacillating than the claimants of the doctrine of evolution. With the confidence he reposes in his coterie of evolutionists, his opposition to the statement of Darwin presented in my first article, that "alcoholism is transmitted through three generations, and the families of drunkards die out at the fourth generation, after having gradually sunk in the scale of degeneration, both physical and intellectual," is not apparent in view of his faith in the preeminence of reason over authority. My opponent claims that "no man can truthfully say that Charles Darwin has anywhere written that *acquired* alcoholism is hereditary." That was not the quotation from Darwin, but that alcoholism was transmissible through three generations unlimited by the contingency of an acquired habit. By perverting the statement of this evolutionist, supported by revelation in the declaration of the Almighty himself, "visiting the sins of the parents upon the children unto the third and fourth generation," and in my former article was claimed to be an expression of hereditary law, Mr. Irwell reminds me of the fabled animal of ancient lore, that donned the skin of a lion.

The assertion made by the reviewer "that the introduction of the Almighty and Abraham does not seem to me to aid scientific investigation," conveys the impression of their inferiority in comparison with his trusted friends—the Evolutionists. Yet when Romanes came down toward the end of life, like the Prodigal, he returned to his Father's house, and embodied in his writings the preeminence of God above every name. He evidently fails to see the harmony of science with revelation, and "is given up to his idols," reminding one of the reply made to another boy, who had said: "His father was a member of church," replied: "My father was, too, but he wasn't doing much in that line."

I am heartily in sympathy and appreciation with my rival in "refusing to follow my lead in the realms of theology." In the expression of this sentiment, he conveys as much wisdom as is anywhere embodied in his review. I am not a leader, and possess no capacity for leadership in theology, law or medicine. I am simply a humble disciple of Æsculapius, sitting at the feet of the great teachers, who have adorned the profession, seeking to gather at least some instruction by which I might aid my coadjutors in lessening the ills of human existence.

In my previous article I presented the following extract from the quotation taken by Mr. Irwell from Dr. Adami's paper: "That alone is inherited which is the property of the individual at the moment he becomes an individual, which is a property of the germ plasma, from which he originates." In my comments on this statement, I said: "This is certainly a truism, and accepted as a fact, it seems perfectly plausible to assume that any element by which it was infected would be transmitted to the fetus, and in the case of syphilis on the part of either or both parents would manifest its presence as it had been revealed in the autopsy of a seven months' fetus." This syphilitic element certainly becomes a property of the germ plasma, which Dr. Adami justly claims as the property of the individual.

In the colossal Encyclopedic Medical Dictionary of Dr. Frank P. Foster, editor of the *New York Medical Journal*, hereditary syphilis is defined as "a syphilis transmitted at the time of conception, either through infected semen of the father or an infected ovum of the mother, or through both." This lucid signification of this form of the loathsome malady does not convey the idea of being an acquired disease, except through heredity, and conflicts with the statement of Dr. Adami that "there is no such thing as hereditary syphilis."

Mr. Irwell apparently gathers an immense amount of comfort from this sentence in Dr. Adami's article: "Any disturbance due to influence affecting the individual from without while in utero is acquired." That is a self-evident

proposition, since no individual exists until after the union of the two elements involved. The doctor would undoubtedly classify maternal impressions as an illustration of this disturbing influence.

A diathesis may be developed by habits of life, unhygienic conditions or environment, yet it also represents a congenital condition originating as the result of inheritance.

While the claim of Mr. Irwell, that the convictions entertained and expressed by some writers may be due to a failure in differentiating between the results of heredity and a habit acquired by association or imitation, may be true, yet it is a question whether this propensity toward the establishment of the drink habit may not be largely the outcome of inheritance. The assumption made by my opponent in seeking to lessen the importance of heredity by reference to the fact that "lectures devoted exclusively to heredity are not usually given in American medical colleges," and "that treatises on heredity for physicians are not numerous" is a truism, yet it does not detract from the importance and value of the subject. This assertion also applies to the topic of etiology of which heredity forms only a part.

The statement made in Dr. Adami's paper, "To judge from the medical press, we medical men care for none of these things," is confronted by Davis (*Chicago Journal of Nervous and Mental Diseases*) Magnus Huss, Thompson de Kapein (*Arch. de psychiatre*), Faguet (Heredity in Alcoholism), Louis (Essay on Hereditary Diseases), and many other authorities. These representative men of science with those already cited in my previous article are certainly sufficient to indicate the claim that physicians are not only willing but have made the study of heredity a subject of great interest and profound investigation.

In the concluding paragraph of his article Mr. Irwell says: "I have never asserted that acquired characters cannot be transmitted." This would be superfluous, as the idea by transposition is embodied in his subject—acquired characters are not hereditary.

"Although I attach little importance to authority as compared with reason," writes Mr. Irwell, who in utilizing a vast amount of this material in his discussion, evidently "shows his faith by his works." "I feel justified in resorting to a little evidence of this kind." He says: "The leading neo-Lamarkians claim that the blind fish found in caves are progeny of fish that became blind by accident."

As exercise promotes development in the physical, intellectual and spiritual sphere of man, the converse must necessarily be true. These are facts in science, which I shall constitute the basis and the premise of my syllogistic reasoning. "The blood is the life" is an infallible proposition, alike in nature and revelation. Without it there is no functional activity in any organ of the body. It is essential to the performance of the digestive process, and absolutely necessary in the accomplishment of intellectual labor. The power of thought initiated in the cerebral cortex is materially enhanced by culture, illustrated by the greater ease by which the student accomplishes his task a few days after his admission into the school room. If he devotes his attention solely to some physical pursuit, there is declension in the character and strength of his intellect. The same remark applies to the muscles, when confined by fracture appliances, revealed in their softened and debilitated condition, that unfit them for usefulness, and if continued for a long period would eventuate in their complete disqualification.

After a woman has passed the climacteric, less blood enters the organ, less nutriment is supplied, and the uterus becomes atrophied. Accepting this statement of facts, it is reasonable to conclude that fish inhabiting dark caves are blind from the absence of the stimulus of light, rather than from the result of accident.

While I entertain a high regard for scientific men of thought, and enjoy the literature of profound research, represented by these brilliant evolutionists, yet I prefer to accept the results of medical investigators whose brows are crowned with laurels in the temple of fame.

---

## THERAPEUTICS OF POTASSIUM COPAIBATE.*

BY LOUIS KOLIPINSKI, M.D.,
OF WASHINGTON, D. C.

FOR nearly two centuries copaiba has been the standard internal remedy for the treatment of specific urethritis. Recommended by almost all writers, its popularity has never diminished. It has made fortunes for charlatans. Its use has spread into the hands of the laity.†

The first to recommend copaiba in venereal disease in such a manner as to make its use part of a system of treatment was Daniel Turner, M.R.C.P.‡ He writes: "In my own Practice after I have sufficiently Purged of the Virulency, or as the Quantity and Color of the Flux shall indicate; I usually finish with ℥i of the Balsam Copaiba called commonly Capivi, given at several times; *vel sub forma Electuarii cum Conserv. fruct. Cynosbat. vel instar Pastae albae. cum sacch. alb. praep. sumendo Alterutruis Quant. Nuc. Mosc. Maj. mane atque vesperi, ventriculo vacuo.*

"One Pot of this Composition hath very frequently completed the work; or if there be occasion, I repeat it once, twice, or perhaps thrice, if any Remains of the Gleet should so require, and this Remedy I prefer to any of the Terebinthinate Ones, or indeed any other of the natural Balsams whether *Gilcadense, Peruanum Opobalsamum,*

*Read at the meeting of the American Therapeutic Society, held at Washington, D. C., May 12, 1903.

†On the authority of the U. S. Treasury Department, Bureau of Statistics, there were imported into this country in 1899, 210,223 pounds of copaiba; in 1900, 202,092 pounds; in 1901, 212,082 pounds; in 1902, 235,194 pounds.

For the fiscal year 1902, 213,645 pounds came into the port of New York from the following countries: Brazil, 89,036, England, 60,438, Venezuela, 47,531, Colombia, 12,623, Germany, 2,300, Salvador, 253, Costa Rica, 96, Nicaragua, 378.

‡Syphilis, a Practical Dissertation on the Venereal Diseases, etc., London, 1717.

*Tolutanum* (all used by some Practitioners for this purpose) because I find it heals and binds less than the last; Nor is it such a Tell-tale as the former, where the Chamber Pot by its smell, discovers what has been done all over the House; besides it is less Naseous to many People's Stomach than the Common Turpentine, especially if taken in the Way I have here prescribed it. Indeed I have often wondered so few of our Writers have taken Notice of this noble Medicament, in finishing the Cure of *Claps* and of *Gleets* arising from thence; for which I believe very few Remedies can compare in the whole Physical Republick, and they who know rightly how to time it, may perform more in a Week than by all the other Methods now used, in a Month. I am sure I have known one Single Ounce thereof effect more in some of these Cases than a whole Pound of Turpentine, mixed up too as Mr. Wiseman directs cum *Pulv. Jalap. Crem. Tart.* et *Sale Prunel.* or than the *Chios* and *Cyprus* Turpentine taken alone in large Quantities."

Turner thus used copaiba only in the stage of decline of gonorrhea—an error copied from book to book since his time.

Of the few who have condemned copaiba may be mentioned J. L. Milton.* He writes with much repugnance but little reason. He warmly commends Thorn's preparation, to be next described, without apparently having had any practical experience with it. His praise, however, is both just and merited.

Three theories have been produced, claiming to determine the active principle of the drug, or the parts to which its virtues are due, of which the first is that of James Thorn,† M.R.C.S. The following extracts give the substance of this interesting essay: (pp. 7-8.) "The medicine which I have seen used with the best success (in gonorrhea) has been the balsam of copaiba given after the inflammatory symptoms have subsided: but the dislike generally expressed by patients on taking it,—the circumstance of its not being available in the inflammatory stage, detract from the value of this remedy. From these circumstances I was induced to try what would be the result of an analysis of the balsam, conceiving that its active principle might be very much concentrated and rendered more extensively useful when separated, than in the present form. By distillation, an essential oil was produced of a light green color having a most unpleasant smell and taste; it specific gravity being 0.876 to 1,000 water, leaving a brown resinous extract, quite soft, but becoming hard and brittle when cold; nearly tasteless and inodorous, soluble in ether and pure alcohol. The proportions obtained from two ounces of the balsam of copaiba were: eleven parts essential oil to five of extract, the respective merits of which I shall hereafter mention; and from the result I feel convinced that by separating the essential oil from the resinous extract, a very irritating and obnoxious part of the balsam is got rid of; and moreover, in the extractive resin all the virtues of the copaiba beside. . . . In the first stage (first twenty-four hours) may be given extract of copaiba with the most decided advantage in very large doses, from 15 grains to a scruple three times a day. . . . In the stage of gonorrhea in which the inflammatory symptoms are fully developed, which is generally within two or three days from the first appearance of the symptoms. . . . Unless the inflammatory symptoms are very excessive, and there appears any disposition from the previous history of the complaint to swelling of the testicle. I have given the extract of copaiba from 10 to 15 grains three times a day when first applied to, while the patient is affected with all the inflammatory symptoms." (p. 21.) " . . . It must be obvious that I do not recommend the extract of copaiba to be given while there is inflammation of the testicle or epididymis. On the contrary, it is better to resort to those means which will promote the discharge from the urethra, together with abstraction of blood from the scrotum, and such depletory measures as the circumstances of the case may require." (p. 23.) "The success of the application of the extract of copaiba in the inflammatory stage of gonorrhea may be doubted by many, from the circumstance of the balsam having been found not only of no use, but very prejudicial while inflammation of the urethra existed. But the sceptic on this point has only to take into consideration the difference between the preparations: that in the one there is an essential oil extremely irritating, and possessing qualities as hurtful as I can well conceive anything to be, for gonorrhea: while in the other there is only the pure resinous extract freed from the essential oil." (p. 45.) "There are some advantages, however, as a therapeutic agent, the extract possesses over the balsam, which it may not be amiss to mention more fully than has been done in any former part of this work. The first, which is that of its not producing the nausea, any disturbance of the alimentary canal, or the eruptions on the skin, which the balsam does." (p. 50.) "My opinion is that the frequent cause of the failure of balsam of copaiba, in curing gonorrhea, may be attributed to it (the variation in the quantity of extractive resin found) and that the good effects have been in proportion to the quantity of extractive resin the balsam contains."

Thorn thus was the first to use the acid resin—copaibic acid under the name of extract of copaiba. In a later work he commends it to be given combined with an alkali, hence practically a soluble copaibate. Thorn was correct in recognizing the curative power of copaibic acid in the disease when used from the beginning, also that the mass is more agreeable to take than is copaiba. In error, however, when he thought the

*On the Treatment of Gonorrhea without Specifics, London, 1862.

†Observations on the Treatment of Gonorrhea by a New Preparation from the Balsam of Copaiba, with Illustrative Cases. London, 1827, p. 57.

volatile oil acrid and irritating or that the acid resin will not disturb the alimentary canal or cause skin eruptions.

The second theory is that of the volatile oil. H. M. J. Desruelles* relates that in 1826, M. Dublanc, a distinguished chemist, thought the resin of copaiba is inert and conceived the idea to distil balsam of copaiba and to extract a volatile oil. This oil, to which a few drops of sulphuric acid is added, assumes a red or red-brown color and loses some of its bad odor and taste. The volatile oil with and without the addition of the acid was tried by Desruelles with success. In value he held 4 grams of the volatile oil to equal 16 of copaiba. M. Cullerier at l'hopital du Midi had similar good results.

The third and last theory is that of Bernatzik,† of Rocco da Luca and Amato, 1884, quoted by E. Finger.‡ They studied the action of copaibic acid and of copaiba oil on gonorrhea and came to the conclusion that neither of these two constituents when isolated has the action of the natural combination.

Bernatzik, in his much quoted article, says, when we recollect that the oil of copaiba stands in high physiological relationship to the resins; that therapeutically almost as active as they, though at the same time it is milder and hence mitigates the action of the resins on the intestinal and urinary tracts without detriment to the curative properties, one is justified in preferring the balsam in therapy to either of its constituents. The ethereal oil is the natural and most appropriate therapeutic co-agent and excipient and adjuvant to the resins. They, according to these recorded observations, act much too violently even in moderate doses, and in many cases, to increase the same or to continue their use is simply impossible. The greatest effect is to be found in using the thin variety of the balsam as being milder in action, due to more of the oil and less of the resin.

This study occupies itself entirely with the effects of the acid resin in alkaline combination. From both a lack of knowledge and experience the writer does not venture an opinion on the medicinal merits of the essential oil. The actions and effects of copaiba are too well-known to be described or discussed.

Copaiba, popularly and incorrectly called a balsam, is an oleoresin. Its sp. gr. is from 0.950 to 1.000 (Watt's Dictionary of Chemistry, 2nd ed.). It contains a levorotatory terpene (copaiba oil) $C_{20}H_{32}$, boils at 250° C. to 260° C., sp. gr. 0.900. The terpene from ordinary copaiba yields a crystalline hydrochloride $C_{20}H_{32}$ 4 HCl. The terpene from Maracaibo copaiba yields terephthalic acid on oxidation. It also contains (A. Wurtz—Dict. de Chimie pure et Appliqueé) two acid resins, the chief being copaibic acid $C_{20}H_{32}O_2$— it crystallizes. In composition it is the same as abietic acid. The other resin is viscid and uncrystallizable and seems to be a product of the alteration of the former.

Copaibic acid forms with bases combinations yet little known, soluble in alcohol and ether, insoluble in water. Potassium and calcium yield non-crystalline; lead and silver, crystalline salts. The amorphous resin seems to have the same chemical composition as the crystalline resin. It possesses the special character that it can be produced by the oxidation of the essential oil in contact with water, while the crystalline resin is produced only by the action of vegetation.

Metacopaibic acid $C_{22}H_{34}O_4$ has been found in Maracaibo copaiba and oxycopaibic acid, $C_{20}H_{28}O_3$ in Para copaiba.

Copaiba holds a variable quantity of essential oil. In some samples 30 per cent. was found, in a greater number, very little or none at all. The amount of volatile, which is given at 40 per cent. to 60 per cent. is higher than any copaiba examined by the writer. Probably most of the drug kept and dispensed in the shops contains very much less.

Potassium copaibate was prepared in the following manner: eight parts by weight of copaiba are mixed with one part of potassium hydrate dissolved in a small quantity of water. On agitation or stirring, saponification results. The mixture is allowed to stand for a few days. Three layers are then found to have formed. The uppermost contains the volatile oil, if present. The middle one is potassium copaibate; the lowermost is the residue of uncombined alkali in water. Thus made it has these properties: It is a clear fluid of reddish brown color. At 50° F. its consistency is gelatinous; at 63° F., thick and oily; at 70 to 80° F. it is quite liquid. Its taste is acrid and peppery; its odor similar to that of copaiba. The reaction is alkaline. It dissolves in alcohol, ether and chloroform. Its solution in water is opalescent; which soon becomes milky white from composition.

The alkaline copaibates have properties much alike. Potassium copaibate was adopted as the best of its kind because it is a more stable compound; is more convenient to handle; is more agreeable to take and more certain in its effects than the copaibates of sodium and of ammonium. The dose of potassium copaibate is from 50 to 150 grains a day. It is best taken in gelatin capsules No. O.O., so-called ten-grain ones. Four to twelve capsules represent the daily amount. The average man will tolerate two capsules thrice repeated. The robust with strong digestive powers, twelve. The weakly and those easily purged will not be able to take more than four for the same period of time.

The untoward effects of the copaibates are similar to those of copaiba, but not so severe, frequent or constant. A patient may give up copaiba ad nauseam, not so the copaibate. The after-taste, eructations and gastric oppression are but seldom mentioned by those taking it. Lumbar pains do not appear or are so slight as to escape comment. Overdoses produce strong laxa-

* Histoire de la Blennorrhee Urèthrale, Paris, 1854.
† Vierteljahrsch. für die Prakt. Heilkunde, 1868.
‡ Die Blennorrhieo der Sexual Organe und ihre Complicationen. 3. Ed., 1893.

tive effects without corresponding diuresis. Those of costive habit find the bowels regulated. The proper dose apportioned to the individual seems to improve the digestion; is without purgative effect and increases the urinary secretion.

It produces skin eruptions—roseola and urticaria—as does copaiba and these occur only in susceptible individuals from any dose, large or small. In a daily experience of several years, four such instances of drug exanthem were observed.

The following is the history of one showing that it remains with the judgment of the practitioner to continue the remedy or not.

*Case I.*—Waiter, aged twenty-three years, married. A gonorrhea, first infection, of three weeks. Treatment: Self medication with injections and copaiba emulsion. Present condition: purulent urethral discharge, pus and shreds in the urine; urination urgent and frequent. A copaiba roseola, slight on face and neck, more abundant on forearms and hands; much itching; has been out some days. He took two capsules of the copaibate at noon and the same number at 4 o'clock in the afternoon. In the evening the rash was much intensified; the patient greatly frightened. The roseola had changed to a very active urticaria. He complained greatly of the itching. The face, neck and hands were swollen. The copaibate was suspended, and the next day the second eruption had disappeared, nor did it or the first one return. He resumed the copaibate at once taking twelve grains every three hours. Treatment ceased a week later, patient being cured.

*Case II.*—A young man with acute gonorrhea, first infection, complicated with peri-urethral abscess posterior to the corona glandis, developed a very abundant rash within two days from taking the average doses of the copaibate. On the limbs the roseola was discrete and sparse; on the trunk, especially the whole of the anterior surface, it was very densely placed. It disappeared on omitting the copaibate and substituting sandalwood oil. In three days the patient, of his own volition, resumed the copaibate in the original dose; the exanthem did not reappear.

The copaibate of potassium is a soap. Used as such it will be found to be actively detergent, antiseptic in a moderate degree and of an odor more or less aromatic. It is useful in some cutaneous diseases. The writer has cured with it chronic eczema of the hands and of the legs. Acne vulgaris and acne rosacea are improved by applying it undiluted and removing it by washing with water as soon as burning begins to be felt. Two or three drops to a fluid ounce of water offers a solution which is an agreeable cleansing and palliative spray in catarrh of the nose and throat. In laryngeal catarrh and in the hoarseness and enfeebled voice of singers and speakers it has been much praised by patients. Applied undiluted on pledgets of gauze on ulcerating cancerous tumors it removes fetor, arrests purulent and putrid discharges and prevents hemorrhage. Its internal uses are like those of copaiba; its more particular actions are these. In anuria of the non-obstructive form it has been successfully used by the writer. In acute cystitis it often effects a cure and its power is more marked in women than in men. Chronic cystitis is palliated; pain and tenesmus relieved. The urine is less loaded with pus and mucus; decomposition is less active.

In diseases of the respiratory tract, of the stomach and of the intestine, no action worthy of note has been observed. In cholelithiasis or gall-stones it has been found very useful. It compares favorably with the treatment by olive oil or the use of Carlsbad water, whether in the latter instance the patient be treated at home or is able to sojourn at this or that mineral spring. Not alone does the copaibate prevent attack of biliary colic but also when this has occurred the resultant jaundice is shortened in duration; the period of prostration is much lessened and recovery very much sooner attained. Gall-stone disease is common and the cases suitable for surgical operation are comparatively rare. Therefore the multitude that suffers from minor gastric disturbance, transient pain and occasional attacks of acute obstruction and expulsion is the proper class for which the copaibate can be commended. How the copaibate acts is obscure. It is not a solvent of a biliary stone.

The following short record narrates a case of infrequent severity:

*Case III.*—A young mother, with an infant of six months at the breast, had had from one to three attacks of hepatic colic every week for five months. Formerly of stout figure she had grown weak and emaciated. Some paroxysms were succeeded by jaundice, the greater number were not. The fundus of the gall-bladder on palpation was enlarged and very tender. As medical treatment had so far failed, the patient was willing and anxious for surgical relief, but was deterred from this step by the fear of ill health in her nursling. She took the copaibate steadily for three months. The attacks ceased, and at present after a lapse of eighteen months she has remained in apparent perfect health. In this one the diuretic power is recorded.

*Case IV.*—A young, delicate woman had a gall-stone to pass without any intense pain: the whole was over in half a day, and she did not call for medical aid. She had had a like attack two years before. The next day jaundice appeared. She was so weak as hardly able to be about. There was no desire for food. She was given 12 grains of the copaibate four times a day. The jaundice disappeared completely in forty-eight hours.

The chief use of the copaibate is found in acute gonorrhea. In the stage of gleet it is unavailing. Of the copaibate in specific urethritis it may be said: the proper dose can be steadily pushed for from one to three months without unpleasant reaction. Occasionally a copaiba erup-

tion appears on beginning its administration due to idiosyncrasy. The copaibate is a powerful diuretic increasing the secretion of urine 25 per cent. This effect cannot, however, be prolonged indefinitely in all cases. In a few instances it was observed to set up a polyuria. This polyuria disappears in a week, on the omission of the medicine. It is possible, however, that a grave form of insipid diabetes may begin and in old subjects with chronic inflammation of the bladder or other portion of the urinary tract life itself may be thereby endangered.

The course of an uncomplicated case of gonorrhea treated with the copaibate terminates often in complete cure in from one to two months.

In an early urethral infection, the copaibate if begun at once may in rare examples produce a cure in a few days.

Where a heavy purulent or sanguineopurulent discharge shows itself, and the whole organ is hot and turgid, it mitigates in a high degree the scalding pain of urination and chordee is hardly ever felt. At the end of two or three weeks the discharge begins to abate and often somewhat suddenly.

The chief merit of the copaibate is to be found however in that it reduces the danger of complications to a minimum, so that gonorrheal bubo, epididymitis, Cowperitis, prostatitis, vesiculitis, cystitis, and stricture are seldom seen to arise. Upon the prevention of gonorrheal rheumatic infection an opinion cannot be expressed for want of cases so far encountered.

Potassium copaibate possesses the virtues commonly assigned to copaiba with some special ones due to its solubility. These are its uses on the skin and mucous membranes for its alkaline, detergent and antiseptic properties; its lesser tendency to disturb the economy by producing gastric and intestinal irritation. Further, it is much more palatable than copaiba. It is true that it produces the copaiba exanthems, but this need not of necessity cause its discontinuance.

## MEDICAL PROGRESS.

### MEDICINE.

**Influence of Adrenalin on Muscular Contraction.**—At the close of an interesting paper dealing with the effect of adrenalin and other glandular products upon muscular contractions, J. IOTEYKO (Jour. Méd. de Bruxelles, July 9, 16 and 23, 1903) thus sums up the subject: (1) The richer the muscle in sarcoplasm the more energetically does adrenalin act upon it. It is a sarcoplastic excitant. (2) Other glandular products, such as extracts of the thyroid gland, the hypophysis, testicle and ovary have a similar influence. (3) The term "physiological poisons" is proposed for the products of these glands, which, acting chemically upon muscle tissue and especially upon the sarcoplasm, have power to augment the muscle tonus. This increased tonus is most apparent when the muscle is subjected to electrical excitation; a condition most favorable to contraction having been created thereby. It may be concluded that the tonus brought about chemically in the muscles by these glandular products is a physiological phenomenon which facilitates the action of the nervous stimuli and constitutes a preparatory stage to contraction. Thus these substances might be called "sensibilisatrices" their rôle being the augmentation of the sensibility (receptivity) of the muscle to the nervous stimulus.

**Typhoid Paralyses.**—Of the forms of paralysis depending upon typhoid infection, monoplegia is most frequently seen according to S. CERAULO and G. GRANOZZI (Gazz. Siciliana de Med. e Chir., July 2 and 9, 1902); hemiplegia and paraplegia being of rare occurrence. The appearance of paralysis seems to bear no relation to the gravity of the disease; this complication sometimes occurring in the lightest cases, while the most severe may run their course without any form of paralysis. Monoplegia is usually preceded by a sense of numbness, weakness and coldness followed by pain, which may be very severe and persist after the paralysis has subsided. The latter may last from a week to several months and is accompanied by abolition or diminution of tendon reflexes and sensibility. Hemiplegia may appear in the course of the disease, but usually appears during convalescence; and its onset is generally sudden. Paraplegia also makes its appearance, as a rule, during convalescence. In a few cases paralysis may extend to the pons and give rise to the symtoms of Duchenne's subacute general paralysis; in others, one of the cranial nerves may be involved; and in one instance, paralysis of one of the abductors of the vocal cords necessitated tracheotomy. Lastly, disturbances of speech may occur in the course of the disease or during convalescence; and children are especially prone to aphasia. As to the pathogenisis, a toxic neuritis or lesion of one of the nerve-centers is generally responsible for the monoplegias. Not so, however, with the hemiplegias, which may be ascribed to thrombosis or embolism of the sylvian artery or else to hemorrhage. Paraplegia is, for the most part, due to polyneuritis or to a medullary lesion. The transitory aphasias of children—generally of toxic origin—are to be distinguished from those of adults, which are often associated with obliterating endarteritis of the slyvian artery, embolism or thrombosis. The prognosis is good in most cases of typhoid paralysis. Intoxication being directly or indirectly responsible for such affections, elimination of the toxins should be promoted by free diuresis and other measures. Tonic treatment, massage, baths and electricity all contributed their quota toward the cure of typhoid paralysis.

**Vaccinal Delirium.**—The description of three cases of delirium following vaccination is given by E. RÉGIS (Jour. de Méd. de Bordeaux, July 26, 1903), as reported to him by three of his confrères. All, he believes, were of the type of toxic and infectious delirium. The initial headache and fever were followed by delirium with terrifying delusions; nocturnal only, in the lighter cases and persisting during the day in the more severe. The delirium appeared in each case during the inflammatory period following vaccination and rapidly disappeared with the suppurative stage.

**The Fixation Function of the Liver.**—As the result of a series of experiments, A. PI Y SUÑÉR (Rev. de Cien. Méd. de Barcelona, No. 4, 1903) has reached the conclusion that elimination by the urine of derivatives of hemoglobin does not occur when the liver cells are in normal condition; these substances being intercepted and held—or "fixed," as the author expresses it—by the liver and converted into biliary coloring matter. Injections into healthy animals of hematoporphyrin in solution failed to induce the appearance in the urine of the spectroscopic image characteristic of that pigment; but in animals whose livers were dam-

aged by prolonged feeding with small amounts of phosphorus, such injections were followed by free elimination of hematoporphyrin.

**Immunization Against the Plague.**—Immunization against this disease by means of attenuated cultures of the plague bacillus has lately been made the subject of experiment by W. Kolle and R. Otto (Deut. med. Woch., No. 28, 1903). They failed to find any benefit resulting from the use of the Haffkine method and showed that the immunity, when present, lasted only about six weeks. The authors believe that the injection of avirulent living cultures of the plague to be the only method of effectively immunizing against the disease. They secured avirulent cultures by long cultivation at 40° C. of a particularly non-virulent culture. Three loops of this culture, which is more than 3,000 times the dose of a virulent culture, could be injected into guinea-pigs without producing symptoms. Complete immunity could be conferred on laboratory animals which lasted for months by a single injection, with no signs of infection and merely a small increase in the number of plague germs at the point where the injection took place.

**Auscultatory Percussion to Determine the Size of the Heart.**—Some years ago it seemed as if we had acquired a valuable aid in physical diagnosis by combining percussion with auscultation either by means of the ordinary bimanual stethoscope or the phonendoscope. It was even announced that the different chambers of the heart could be marked out upon the chest-wall with considerable accuracy. Much of the enthusiasm, however, is apt to subside after one reads the article of F. Moritz (Münch. med. Woch., Aug. 4, 1903). It appears that this author has compared the figures he percussed with the X-ray shadow and has found the former to be wrong in nearly every instance. Heart-shaped tracings can be projected upon many different parts of the body for the change in sound depends upon a variation in the tension of the skin and not upon any underlying organ. The method is so unreliable that he cannot warn enough against its use.

## SURGERY.

**The Epidemic Nature of Appendicitis.**—A very complete monograph on appendicitis by Rostovtzeff forms an important contribution to the subject. He does not recognize the epidemic nature of the disease, contrary to N. Golouboff (Prakt. Vratch, No. 29, 1903), who in 1897 put forth the view, as based on clinical data, that inflammation of the vermiform appendix was an epidemic infectious disease. In this opinion he is supported by no less an authority than the famous French surgeon, Lucas-Championnière, who considers appendicitis as a new disease of an undoubtedly epidemic character and especially prevalent in England and in the United States. Prof. Charrin, of Paris, considered the subject important enough to conduct a series of laboratory experiments, the results of which he embodied in a "Report on Experimental Epidemic Appendicitis." There is no doubt that many of the most prominent surgeons seem to be inclined to consider appendicitis as an epidemic, infectious disease, and the more the disease is being studied the stronger becomes this view. Dieulafoy goes so far as to call appendicitis maladie toxi-infectieuse. The author finds that in appendicitis, as in other infectious diseases, there occur icterus, acute nephritis, multiple arthritic inflammations, etc.; he even observed in two cases enlarged spleens. In contending the author draws the following: (1) Appendicitis is an infectious disease. (2) In many of the cases appendicitis appears as a primary, independent affection of the appendix, in the way that tonsillitis represents an inflammation of the tonsillary glands. (3) During the last eight to ten years the number of appendicitis cases has increased progressively, taking the character of an epidemic, or even endemic prevalence. (4) This prevalence is of a distinct, undoubted nature, as observed by Sonnenburg in 1899, in certain localities in Berlin and Frankfort.

**Filling Bone Cavities.**—The most successful method heretofore devised for filling up cavities in bone produced by operation or otherwise, has been by means of the decalcified bone plates of Senn. Barth and Valan were able to show, however, that only a connective tissue scar resulted from the implantation of decalcified bone, while the insertion of macerated or calcined bone was followed by the formation of new osseous tissue which completely restored the defect in the skeleton. The activity of the osteogenetic process in the newly implanted area depends mainly on the inorganic bone salts present which are made use of in the formation of the new bone. Valan has also shown that all the calcium salts exert a favorable influence in this process, and the activity of the latter is directly proportionate to the similarity of the chemical relations between the implanted calcium salts and the inorganic substances in the bone. The spongy character of calcined bone also favors penetration by the osteogenetic elements. Practical application of this theory has lately been made by G. Fantino and A. Valan (Archiv f. klin. Chir., Vol. 70, No. 3) in some 40 cases where bone cavities existed as the result of necrotomies or tuberculous processes. Complete disinfection of the cavity was obtained by thoroughly scraping out the cavity and then filling it with a 10-per-cent. emulsion of iodoform glycerin. This was brought to a boil by inserting the thermocautery point for a minute or two, and bacteriological examination proved this to be a most effective measure. In clean tuberculous cases the cavity may be filled up at once, but after necrotomies it is better to wait a few days, until it is certain that the wound is running an aseptic course. The authors employed the os spongiosum of the calf in their work, after prolonged maceration and boiling and then calcining. The cavity is entirely filled up so that no vacant spaces remain. In cases where the neighboring soft parts are healthy the wound may be entirely closed by suture, and here the process of substitution has been observed to occupy only four months or even less. In cases of acute osteomyelitis and suppurating tuberculous processes failures were often noted on account of the inability to maintain the asepsis or to completely fill all the crevices. Success was finally obtained with a mixture of the bone ash and a compound of thymol and iodoform (1:2), equal parts. This combination is fluid at 75° C. and of almost stony hardness at body temperature. After six months it was found in one case that the implanted material had largely disappeared, the new growth of bone having almost completely absorbed it. It is important that the wound and its surroundings be kept absolutely dry. In all the cases, taken together, the results were almost uniformly good and the process of replacement was complete in from three to eight months.

**Cartilage Changes in Tuberculous Joint Disease.**—For many it has remained an undecided question, whether the changes in the cartilages in a tuberculous joint were of a retrogressive or a progressive nature. A recent contribution to this subject has been made by Schablowski (Archiv f. klin. Chir., Vol. 70, No. 3), who had the opportunity of examining a large number of specimens, principally resected tuberculous knee-joints, and several cases of gonorrheal and syphilitic gonitis. A summary of his descriptions shows that, aside from the various retrograde changes in the carti-

lage, there are also others of a progressive nature. The cartilage, in certain cases of joint inflammation, does not assume a passive rôle and become substituted by connective tissue, similar to the process which takes place in a thrombus, but takes an active part in the formation of the connective tissue. He found that the cartilage cells in some instances became converted into fibroblasts, which increased in size toward the surface. At the same time the cartilaginous spaces also enlarged until they finally were in direct communication with the overlying granulation tissue and also became invaded by vascular processes from the latter. From this time on there is a rapid increase of cells within the spaces, until the cellular contents of the latter have become an integral part of the granulation tissue. He was unable to distinguish any marked differences in the cartilaginous changes on the articular aspect from those on the bony side. A conversion of cartilage cells into pus cells or red blood cells was never observed.

**Diagnosis of Thoracic Tumors.**—A practical method for the diagnosis of malignant intrathoracic tumors is suggested by A. FELD (Deut. med. Woch., 1903, No. 28). He has observed two cases in which the diagnosis was made from the finding of particles of tumor tissue in the sputum. In all suspected cases where hemorrhagic sputum is present he advises their examination against a black background for small bits of tissue, which should be isolated and again viewed after proper preparation under the microscope.

**Protection Against the X-rays.**—The danger to which an operator is exposed by employing his own hand or arm as a test object in gauging the quality of his tubes, has led to the production of numerous protective devices. None of these has fully met all indications. CARL BECK (Berl. klin. Woch., Aug. 10, 1903) publishes an ingenious suggestion, which consists in the substitution of a prepared skeleton of the arm for that of the operator. These bones, properly mounted, may be attached to a piece of pasteboard or other material transparent for the X-ray. The shadows of the bones, just as in the living member, are black when soft tubes are used, and light gray when the harder tubes are employed. This test object may be readily manipulated by the operator, without the latter coming within the radius of action of the rays.

**Osmic Acid in Trigeminal Neuralgia.**—An additional case of this complaint treated by the intraneural injection of osmic acid after the method of Bennett, of London, is reported by J. B. MURPHY (Jour. Am. Med. Ass'n, Aug. 22, 1903). The patient, a man of seventy-six years, presented a trigeminal neuralgia of long standing, resistant to ordinary treatment and incapable of radical operation on account of the general debilitated condition. The injections in this case were given under ether anesthesia, the nerve being exposed directly over its foramen of exist and from 5 to 10 minims of a 1.5-per-cent. solution of osmic acid injected with a hypodermic needle into its substance. A small amount of the solution is also injected between the nerve and its sheath in the bony canal, but care must be taken that none of the fluid gets on the skin. Recovery was uneventful and the wounds healed by primary union. No recurrences of pain have been noted at any time since the operation. The author thinks that the acid probably acts by producing a degeneration of the nerve on the proximal side of the injection, toward the ganglion, rather than by causing a local destruction of the nerve and its terminal filaments. He thinks the former is more likely, because the pain does not subside completely immediately after the operation, as it does when the peripheral nerves are cut, and as it would if the osmic acid produced only a local destructive effect. Instead it subsides slowly and gradually. Moreover, the relief from pain is permanent, which is not the case after peripheral resection. A number of experiments on dogs is now being conducted by the author, which, it is hoped, may throw some light on the changes which take place after the injection.

**Forensic Importance of the Roentgen Rays.**—Every physician who is liable to testify in court should make a special study of Roentgen diagnosis and should be thoroughly conversant with the structure of the epiphyses of the various bones and of the appearance of abnormal bones. D. TROEGER (Friedreich's Bl. f. gericht. Med., Vol. 54, No. 4) believes that an X-ray photograph discloses better than anything else the presence of fractures and dislocations and their effect upon the bony skeleton with exception of the head and vertebral column, where the pictures frequently are not as clear as desired. Foreign bodies, if sufficiently large and of proper material, can be well located. For internal disease, the old methods frequently are more reliable, and absolutely no information can be obtained as to whether a newly born child had breathed during or after birth, or if pregnancy is present. The examiner must have experience extending over several years before his opinion can be accepted as conclusive.

**Spontaneous Cure of an Intussusception.**—A patient, sixty years old, is suddenly seized with severe colic and all symptoms of intestinal obstruction rapidly follow. Seventeen days later diarrhea sets in and a piece of ileum 32 centimeters long is passed. Eight days after this the patient was able to eat solid food without any disturbance. H. SCHRIDDE (Münch. med. Woch., July 28, 1903) was fortunate enough to do an autopsy since the woman died several months later from some pulmonary affection. A narrow, perfect scar was found encircling the ileum 36½ centimeters above the ileocecal valve. Stenosis or adhesions were absent. Like in most cases of intestinal obstruction, the etiology here was not clear. Perhaps foreign bodies play a more important rôle than we think. A thin and weak mesentery is certainly a predisposing cause. Paralysis of a circumscribed portion of the intestines hardly ever occurs, yet irregular contractions of the gut are probably always present and the peristalsis is considerably increased above the site of obstruction. The invagination does not increase in size by a vis a tergo, but probably by excessive peristalsis at the head of the invaginated portion which forces this further toward the anus.

## NEUROLOGY AND PSYCHIATRY.

**Landry's Paralysis.**—This rare and interesting condition was carefully studied by D. ROLLY (Münch. med. Woch., Aug. 4, 1903) who had occasion to observe seven cases. The disease began in all with certain prodromal signs, among which a feeling of lassitude was most complained of. In a short time, paresis of the legs became pronounced and the process then extended upward to the trunk, arms and neck. In two cases the facial nerve was involved and in two the muscles of respiration. There generally is no fever during the onset or at most only a slight rise of temperature and pain does not form a prominent sign at first. Throughout the course the reflexes are absent or much diminished and reaction of degeneration will appear eventually. Ataxia is occasionally present, muscular atrophy appears late and the functions of bladder and rectum are generally normal. No new facts could be ascertained as to etiology, like in so many cases previously published, no cause for this serious illness could be found in some while in others there was the usual history of alcoholism, syphilis and

overexertion. The author looks upon the disease as an acute, ascending neuritis and believes that if the finer nerve-endings in the muscles were to be examined with modern methods, change would always be found. The process has a tendency to creep up along the nerve-trunks into the cord but lesions are found here only if the disease runs a more chronic course. It is often hard to differentiate from acute polyneuritis but here some muscles of each extremity generally escape and the upward extension of the paralysis may be interrupted by days and even weeks of apparent quiescence. The two conditions really belong to one and the same class.

**Clinical Observations in Acute Mania.**—The continuous examination of the blood in four cases of adolescent mania by L. C. Bruce (Jour. of Mental Science, July, 1903), corroborate the observations made by the same author upon the blood of patients suffering from acute continuous mania, namely, in every case there was a persistent leucocytosis, which immediately prior to an attack of mania fell somewhat, then during the attack rose, perhaps as high as 40,000 per c.mm. of blood, and during the periods of interval fluctuated between 13,000 and 27,000. During attacks the polymorphonuclear cells were relatively increased but at other times averaged 60 per cent. Having isolated from the blood of a case of acute continuous mania, a very small coccus, the author found that the blood of the cases of acute adolescent mania (a form of recurrent mania occurring in adolescents) like that of the cases of continuous mania, had the power of agglutinating the organism completely in a dilution of 1 in 20. The serum of six other cases of adolescent insanity which did not present the clinical symptoms of recurrent mania, failed to agglutinate the same organism. The clinical symptoms, the leucocytes and the agglutinative action in the adolescent cases, compared with the same symptoms in acute continuous mania, show a striking resemblance. Everything points to the fact that they are the same disease process modified by the age of the patient. The author treated on purely empirical grounds four cases of adolescent mania with antistreptococcus serum. While injected subcutaneously the serum produced no result, when given in 10 c.c. doses by the mouth, the following were the results obtained: In Case I there was absolutely no result. In Case II, within thirty minutes of the administration of the serum, the patient became quieter, the pulse fell from 10 to 15 beats in the minute, and the temperature fell 1°, but the course of the attack was not arrested. In Case III, within fifteen minutes of the administration of the serum the patient regained self-control, the pulse and temperature fell and the effect lasted for about two hours. A second dose of 10 c.c. arrested the attack. Two subsequent attacks were arrested in the same way. The patient made a good recovery, which the author attributes to the action of the serum. In Case IV the administration of the serum also seemed to arrest the attack. The author believes that this empirical experiment lends support to the view that acute mania is an infective disorder.

**The Pathogenesis of Disease Following Unsuccessful Attempts at Hanging.**—A detailed study of three cases of insane individuals who made attempts at suicide by hanging, but were rescued, was undertaken by W. Alter (Monatsschrift f. Psychiatrie u. Neurol., July, 1903). All three had been cut down after a relatively short time of suspension and resuscitated. They presented absolute unconsciousness. One breathed spontaneously, in the others artificial respiration was necessary. Pulse in Cases I and III good, in II small, in all rapid; the pupils dilated but still react. In from twenty to thirty minutes phenomena of motor irritation set in, in II and III accompanying the improvement in respiration. These phenomena began characteristically in all three with tonic and clonic twitches, passing into general convulsions accompanied by enuresis, biting of tongue and opisthotonus. Remarkable are the kicking movement of the legs and the waving of the arms seen in Case II, in which strangulation had continued the longest. This condition is soon followed by a catatonic rigidity of the entire body with contractions of the sphincters. The motor unrest in Case II is repeated twice in the course of three or four hours. All three cases wake up suddenly but reveal a certain amount of cloudiness of consciousness. A marked amnesia for the attempted suicide and its consequences is present in all cases, lasting for from two to six days. A certain amount of retrograde and anterograde amnesia is present. Motor unrest continues for a variable period. The clinical manifestations, as above detailed, represent, in the author's opinion, an intoxication psychosis of the acutest form—a transitory psychosis in the sense implied by Wernicke They originate in a lesion of cellular elements whose extent is dependent upon the duration and extent of the strangulation, the cells damaged being chiefly those of the cortex cerebri and to a less degree those of the interior of the brain. Hence there result epileptiform attacks, convulsions and the complicated stereotyped motile phenomena, which may be regarded as the result partly of irritation and partly of degeneration. A hysterical individuality can influence but not originate the clinical picture.

**Changes in the Nervous System in Porencephaly.**—The paucity of the cases in which a detailed study of the changes occurring consequent to porencephaly, has been made, imparts considerable value to the investigation made by J. O. W. Barratt (Jour. of Mental Science, July, 1903) on a case of porencephaly which, without any history of traumatism, began at the age of eleven months with eclampsia, and with the continuance of this condition, terminated in idiocy. At thirty years of age the patient was admitted to the asylum and died nearly three years afterward. At autopsy the following changes in the nervous system were found: There was a defect in the brain mantle on the left side involving the aperculum, the island of Reil and the superior temporal convolution. The floor of this area was formed by the subjacent white matter which was very defective in medullated fibers. The left hemisphere was small and had contracted upon the area of defect, the left temporal lobe, seen from below, was also defective in size. The inferior longitudinal bundle on the left side was defective. As the destructive lesion of the temporal lobe was confined to the superior temporal convolution, it follows that the defective nerve-fibers arose in this gyrus. The caudate and lenticular nuclei were unaffected. The left optic thalamus was atrophied, the atrophy involving the lateral median and ventral nuclei (especially the latter) while the anterior nucleus was unaffected. The left optic radiation was atrophied. The atrophy of the optic thalamus was entirely dependent on the cortical lesion, being outside the vascular area involved in the latter. The cortico-spinal and thalamospinal tracts coming from the left hemisphere were markedly wasted in the mesencephalon, pons and medulla in comparison with the corresponding tracts of the other side. The cerebellum was normally developed. The spinal cord exhibited a defect of the left antero-internal column, while the right anterolateral column was of defective width opposite the base of the anterior horn. There was also diminution in size of the right anterior horn. The

lesion was obviously vascular in origin, corresponding very closely to the area of distribution of the left middle cerebral artery—which must have been blocked just beyond the point at which the lenticulostriate branches are given off. The blocking may have been the result of an embolus detached from a cardiac valve exhibiting vegetations, for at the autopsy valvular heart disease of old standing was found.

## HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

**Researches on Tetanus.**—The results obtained by H. MEYER and F. RANSOM (Proc. of the Royal Society, July 8, 1903) include an experimental explanation of so-called local tetanus, a satisfactory interpretation of the period of incubation, the discovery of a form of tetanus confined to the sensory system, called tetanus dolorosus, a theory of the action of tetanus toxin and a definition of the sphere within which the serum treatment of tetanus is effectual. The authors believe they have succeeded in demonstrating that the transport of tetanus toxin to the central nervous system takes place only by way of the motor nerves, on the basis of the following experimental proof: (1) Toxin was found in the motor nerve after subcutaneous injection in a hind leg; (2) the endangered spinal centers can be protected if the passage of toxin along the motor nerve be blocked by means of antitoxin injected into the substance of the nerve; (3) if a lethal dose of tetanus toxin be injected into the sciatic nerve of a cat, the first symptom is a local tetanus of the muscles of the injected limb. This is followed seriatim, after a certain period during which the other hind leg is usually attacked, by tetanus of the trunk, fore legs, muscles of the neck. Such a progression of the disease from the hinder to the fore parts of an animal, can, under certain conditions, be prevented by section of the spinal cord. (4) A dose of toxin which, if introduced under the skin, causes no, or but slight, symptoms, is often sufficient to produce death if injected into a motor nerve. (5) Even when the blood contains a large quantity of antitoxin it is still possible to produce tetanus by injecting toxin into a motor nerve, although, under similar circumstances, subcutaneous or intravenous injections call forth no symptoms whatever. As regards the period of incubation, the authors find that the greater part of this is the expression of the time occupied in the conveyance of the toxin from the periphery along the motor nerves to the susceptible centers. The exaggeration of the reflexes and the characteristic tetanic rigidity of the muscles are due to the action of the toxin on the nervous centers to the entire exclusion of the periphery. In the experiments with injection of tetanic toxin into the substance of the spinal cord, the authors observed, as the first symptom of intoxication, an extremely remarkable sensory disturbance which remained strictly localized, even when the muscular rigidity and the exaggeration of the reflexes were becoming general. In several cases this was so great as to lead to death even before the ordinary symptoms of tetanus were clearly developed. This symptom, known as tetanus dolorosus, consisted in extreme hyperesthesia of some part of the periphery corresponding to the spinal center into which the injection had been made. This overirritability of the pain-reflex apparatus never occurs after simple subcutaneous or intravenous administration of the toxin, nor after administration into a nerve trunk. On the other hand, if the toxin be administered direct into a posterior root the result is pure tetanus dolorosus, thus indicating that the spinal ganglion forms an insuperable obstacle to the transport of the toxin. The reflex answer to the attacks of pain consists in coordinated defense movements, *i.e.*, brain reflexes. The pain apparatus in the spinal cord is so insulated from the motor that an intoxication of the one group cannot go over to the other. The actual movement of toxin in the nervous system takes place not in the lymphatic but in the protoplasm of the nerves. The toxin may possibly be carried centralwards in a sensory nerve, but sensory disturbance cannot be caused in this way. The heart-retarding centers of the vagus are susceptible to tetanus toxin. The tonic rigidity of the muscles and the exaggeration of the reflexes are due to entirely different and independent processes. Reflex tetanus is known to be a discontinuous series of contractions of short duration. The tetanic rigidity of the muscles, on the other hand, is a continuous and gradually increasing shortening, which may, however, regress. This shortening, when it has existed twenty-four to thirty hours is not affected by curare nor by section of the nerve. The theory of experimental tetanus intoxication assumes that the toxin is taken up from the point of injection by the motor nerves. Passing along these it reaches first the motor centers in the cord and excites there an overirritability, so that the discharges, which in the norm only give rise to the so-called muscular tone, become abnormally strong (although not reaching the maximum at first). The extensors and flexors of the injected limb brace themselves more and more and in the hind limbs the extensors tend to overcome the flexors. This, however, takes place gradually, so that for a considerable time voluntary and reflex movements can be executed. It may be said that tetanic rigidity is an intensified muscular tone in the affected limb. The excess toxin is next carried in the fibers of the cord to the motor apparatus of the correponding limb of the other side. After a time, and if enough toxin has been given, the nearest connected sensory apparatus of the reflex arc in the spinal cord is attacked, with the result that the general reflex movements following irritation of the injected limb or its nerve are exaggerated, though from all other parts of the body normal reflexes are excited. The authors found in repeated experiments that when tetanus toxin was introduced direct into a motor nerve, antitoxin, though present in large quantities in the blood, was unable to prevent the outbreak of the disease or even to hinder a fatal issue. They conclude that injected antitoxin does not reach the substance of the nerve fibrils and centers, and that even with highly immunized animals the neurons remain free from antitoxin. As regards the value of the serum treatment of tetanus, it is clear that any toxin which is already in the nerve substance, though not yet in the spinal cord, cannot be reached and neutralized by antitoxin, whether given under the skin or direct into the blood. An attack corresponding to the amount of toxin absorbed by the nerves will infallibly break out and run its course in spite of the antitoxin. On the other hand, the toxin still in the blood and lymph will be rendered harmless by an injection of antitoxin, the absorption of fresh toxin from the infected wound hindered, and in this way an otherwise fatal result may be prevented and the life of a tetanus patient saved.

**The Immunizing Effects of the Intracellular Contents of the Typhoid Bacillus.**—It has been shown by Allan Macfayden that it is possible to disintegrate mechanically the typhoid bacillus at the temperature of liquid air and to obtain the cell-juices of the organism. In inoculation into animals these cell-juices proved toxic or fatal. It was, therefore, concluded that the typhoid bacillus contains within itself an intracellular toxin. The same author (Proc. of the Royal Society,

Vol LXXI, No. 473), in testing the typhoid cell-juices for immunizing and other properties, finds that by their injection into the monkey it is possible to obtain a serum with both antibacterial and antitoxic properties, and that such a serum possesses curative and preventive properties as regards the typhoid bacillus and an intracellular toxin present in the same organism. The author believes that this research has afforded for the first time proof that, in the case of one species of pathogenic bacterium, the intracellular juices of the organism, when injected into a suitable organism, give rise to the production of a serum which is both bactericidal to the organism itself and antitoxic as regards a toxin contained in its substance.

**Cytodiagnosis in Pleural and Peritoneal Exudations.**—The diagnosis of the character of an exuded fluid into one of the serous cavities of the body has received a valuable aid by the examination of the cellular elements deposited in it. This is especially true in tuberculosis, for despite staining for bacilli, animal inoculation, tuberculin test and the more recent agglutination, we still lacked a quick and certain method of diagnosis. A critical review upon the advantages of cytodiagnosis based upon a large number of experiments, is found in the careful dissertation of L. v. Ketly and A. J. Torday (Deutsch. Arch. f. klin. Med., Vol. 77, Nos. 1 and 2). In primary tuberculous pleurisy, the deposit consists of a large number of small lymphocytes mixed with more or less red corpuscles, throughout the entire course of the disease, while endothelial cells occur only in few numbers. The same holds true for secondary, acute, tuberculous pleurisy except that in the first few days there may be predominance of polynuclear cells and endothelial elements. A chronic tuberculous pleurisy can hardly be distinguished from the chronic processes accompanying Bright's disease or heart trouble, by means of cytodiagnosis since polynuclear cells, lymphocytes and endothelial cells occur in varying numbers in both and disintegration very often does not permit one to discern the character of the cells. The ascitic fluid of Bright's disease and endocarditis contains many endothelial cells and later lymphocytes and still later there may be close resemblance to the deposit in chronic, secondary tuberculous pleurisy. The exudate following a pulmonary infarct, if chronic, hardly differs from that of nephritis. Pleurisy due to the pneumococcus gives a fluid containing many polynuclear leucocytes and endothelial cells. Cytodiagnosis is thus of value particularly in the diagnosis of primary, tuberculous pleurisy. An acute onset with marked lymphocytosis is characteristic here. Where the course is chronic, however, one must rely more upon the clinical aspect of the case. Cytodiagnosis will thus aid in giving a prognosis in acute cases, while it will not materially influence the treatment.

**Pathology of Tetany.**—As a result of clinical observation on 77 cases, and careful autopsy on seven, with microscopical examination of the cord and nerve-roots, R. Peters (Deutsch. Arch. f. klin. Med., Vol. 77, Nos. 1 and 2) reports as follows on the anatomical changes in tetany such as is common in children from three months to three years: Tetany is not a functional but an organic disease. Its chief lesion is on inflammation of the extradural connective tissue which invests the dural sac and is continued through the intervertebral foramina around the nerve-roots and ganglia. This external pachymeningitis is really a small-celled infiltration with hemorrhages or else there are fibrinous deposits or colloid infiltrations in disseminated plaques. The vessels are also pathologically altered and bleeding takes place by preference between the ganglia and anterior roots while the pachymeningitis is most marked about the roots, especially the seventh and eighth cervical, the lower lumbar and the upper sacral. Secondarily, an interstitial neuritis and gangliitis develops. The former affects only the extradural portion of both motor and sensory roots; the latter amounts to a proliferation of the intracapsular endothelial cells, with infiltration of round cells and karyolysis of the ganglion cells. The interstitial infiltration and the pachymeningitis itself are characteristic for tetany and the most severe cases have the most intense lesions. Concerning etiology, tetany is probably most often caused by measles, influenza and pneumonia but it is also possible that there is a specific micro-organism or that leucomaines and ptomaines liberated by auto-intoxication exert their injurious influence upon the nerve-roots. In conclusion, a new symptom of tetany is described: If the anode of a current of three or four milliampères is placed upon the chest, and the cathode upon the fifth, sixth or seventh cervical vertebra, rapid twitchings will occur in both upper extremities at each closure.

**Osmic Acid in Clinical Microscopy.**—The undoubted value of osmic acid in clinical microscopy has been repeatedly demonstrated, but has never been widely employed in general daily practice. C. Posner (Berl. klin. Woch., Aug. 10, 1903) calls attention to its use in quickly fixing the living cells of the body fluids, as a substitute for heat or other agents. For this purpose he employs the fumes which come from a few crystals of the acid placed in a dark colored bottle. The stopper of the latter is removed and the object carrier or slide is held over the open mouth for a few seconds, care being taken that the fumes are not inhaled. The preparations are then dried in the air and stained directly, washing or other preliminary measures being unnecessary. The method is very efficient for the examination of the blood but the author has applied it more particularly in the examination of urine. Pus from the urethra shows much more distinctly than with any other method, the intra- or extra-cellular location of the cocci, while the cells are not distorted and the nuclei are very distinct. Urethral shreds, which are ordinarily very difficult to demonstrate satisfactorily, are fixed and stained faultlessly and quickly. The same applies to the examination of prostatic secretion. The method seems to be particularly applicable to the demonstration of urinary sediments,—the outlines of the leucocytes are well preserved and the nuclei are uncommonly well stained. The red and epithelial cells, bacteria and even the crytals remain in their natural condition. It is also possible in many instances, to stain the casts, although the results frequently vary in a way which cannot at present be explained.

**Active Substances of the Colon Bacillus.**—Two principles could be isolated from the bouillon cultures of the colon bacillus by A. Carega (Centralbl. f. Bakt., Vol. 34, No. 4), one a nuclein and the other a nucleo-albumin. The nuclein is a toxic substance with cumulative action; the smallest fatal dose is two centigrams per kilogram body-weight. A specific agglutinating principle against this substance is not formed in the blood-serum. The nucleo-albumin is also toxic but not cumulative; the fatal dose here is six centigrams per kilogram and the blood-serum acquires a specific, agglutinating property. Upon analysis, the nucleo-albumin is found to consist of two substances, a toxophor principle, destroyed by heat, and an agglutinogenous, indifferent principle, not affected by heat. The toxophor group plays no part in the agglutination. It is impossible to immunize rabbits against the colon bacillus with the nucleo-albumin.

# THE MEDICAL NEWS.

*A WEEKLY JOURNAL*

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request thereior accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

## SATURDAY, SEPTEMBER 12, 1903.

### TREATMENT OF ANEURISM.

ONE year ago, Dr. Rudolph Matas, of New Orleans, announced a characteristically ingenious method, which he had devised and put into successful practice, in the treatment of operable aneurisms. Insufficient time has elapsed since the operation was first described to permit accumulation of the statistical data necessary to establish its general value, but that it has proven attractive and serviceable to American surgeons there is evidence.

The following is quoted from Brewer's recently published Manual of Surgery, "Rudolph Matas, recognizing the ready adhesion of sutured serous surfaces, advises after compression of the main supplying arterial trunk incision into the aneurismal tumor, removal of the clots and fibrin, and closure of the arterial orifices by sutures so placed as to ensure broad approximation of the margins of the openings. In sacculated aneurisms he closes the single orifice of communication between the artery and aneurismal sac, *and thus restores the main vessel.* In certain fusiform aneurisms he constructs a new channel by suturing the walls of the sac over a rubber catheter in the same manner as the Witzel method of gastrostomy is carried out. After all of these procedures he obliterates the remaining portion of the aneurismal cavity by closely approximating its walls by suture. He claims that this procedure is safer than the other methods: that the wound heals more promptly and that in some instances the artery is restored to its original dimensions."

A review of a masterly monograph on the operative treatment of aneurism, in the April number of the *Deutsche Zeitschrift für Chirurgie*, by Jacobsthal places one in accurate possession of the best manner of treatment, as determined by comparative statistics. In conclusion he says, "Extirpation is without doubt the ideal method. Unfortunately it is applicable only in chosen cases. If the aneurism is not thrombosed but, rather, thin walled and pulsating, extirpation can be advised only if the tumor is small and of slow growth. If extirpation is not possible the next best treatment is proximal ligation. If consolidation of the sac does not follow proximal ligation, distal ligation is indicated. In those cases where only distal ligation can be practised the prospect of a permanent cure is remote. In far advanced inoperable cases, Macewen's procedure of needling and scratching the aneurismal wall is indicated. Electrolysis and puncture by wire must not be forgotten, as Thorburn has recorded marked improvement in a case treated by the former technic. The value of gelatin injections is not yet definitely decided."

Although these conclusions do not differ from those advanced by most recent text-books on surgery, they are instructive in that they are based upon the usual firm foundation of German statistics. In a word, they show that the surgical treatment of aneurisms has remained very nearly stationary for a great many years. So much the more credit is due Matas for creating a technic which, although gaining recognition here, has not yet penetrated the self-sufficient conservatism of the continent. It is particularly unfortunate for completeness of Dr. Jacobsthal's article that Matas' contribution—the only one published in recent years which appears to mark a distinct advance—should have been wholly omitted from his full bibliographic citations of ninety-four papers referred to by the able author.

What the future holds in store for this operation is a problem that can be answered only by time. Naturally some difficulty might be anticipated in its application to those aneurisms in which, as unfortunately is often the case, extensive atheromatous or calcareous degeneration has taken place. The justice of this criticism, however, is denied by Matas.

It is earnestly hoped that all surgeons having

interest in the operative treatment of aneurisms will consider this technic so that by their conjoined opinions its worth and limitations may soon be definitely known.

### THE LIQUOR PROBLEM IN THE SCHOOLS.

A FACT that is not generally known even to many of those who are deeply interested in the various aspects of the liquor problem—social, ethical, economic, and physiological—is that there has been a Committee of Fifty investigating different phases of this important subject for nearly a decade.

As the result of their investigations a number of reports have been published; the first one of which, The Liquor Problem in Its Legislative Aspects, was given to the public in 1897. This was prepared under the direction of President Charles W. Eliot, of Harvard, President Seth Low, of Columbia, and Hon. James C. Carter, of the New York Bar, who make up the legislative subcommittee of the Committee of Fifty. In 1899 a Volume on Economic Aspects of the Liquor Problem was published as the report of the economic subcommittee, and in 1901 the ethical subcommittee, consisting of Professor Francis Peabody, Dr. Elgin R. L. Gould and Professor William M. Sloane, published Substitutes for the Saloon. The personnel of these subcommittees will serve to indicate how representative in its practical intellectual character is the constitution of the General Committee of Fifty. Physicians who are interested in the liquor problem then, and what physician is not, will feel it a duty not to miss the committees' reports.*

Just at the present time their interest can scarcely fail to be aroused by the report of the subcommittee which had in hand the investigation of the physiological aspects of the liquor problem. The directing members of this subcommittee are Professor W. O. Atwater, of Wesleyan University, Dr. John S. Billings, formerly of the Surgeon-General's Library, now of the New York Public Library; Professor H. P. Bowditch, Professor of Physiology at Harvard; Professor R. H. Chittenden, Director of the Sheffield Scientific School of Yale University, and Professor W. H. Welch, the Director of the Pathological Department of Johns Hopkins University. It is evident at once to anyone who is familiar with American Science that the investigations of such men are very likely to prove eminently helpful in the elucidation of this important problem, and as the treatment of the supposed physiology of alcohol has in the past almost, as a rule, been obscured by prejudice and partiality, it is very clear that this report can scarcely fail to be of very lively interest and far-reaching significance.

The first monograph in the collected report treats of physiological instruction, as it is at present attempted in the public schools. The subject is treated by Professors Bowditch, of Harvard, and Hodge, of Clarke University, Worcester, Mass. They are able to find very little that is favorable to say of present-day methods of teaching and of the approved text-books of physiology as far as regards their treatment of this subject. By a series of what the New York *Sun* used to call "deadly parallel columns" they show how the opinions of standard physiologies have been garbled, important portions omitted and only certain unfavorable passages selected in order to create that peculiar text-book—"The School Physiology"—that shall succeed in satisfying the requirements of the Women's Christian Temperance Union. Even Professor Hodge himself has been quoted to this effect, "Alcohol always lowers working power and in some degree interferes with growth." With reference to this purported quotation, Dr. Hodge is able to deny that it occurs in any of his public writings or elsewhere, so far as he knows. He has certainly not drawn any such sweeping conclusion from his own experiments.

This is only one example of the flagrant way in which scientific and educational confidence has been abused in the making of these text-books. It is no wonder, then, as the collation of the opinions of a number of teachers in many States makes clear, that these text-books do not appeal to them, and, in fact, to many seem rather calculated to produce an unfavorable rather than a favorable effect as regards the cause of temperance. One New York teacher has stated his conviction in the matter very forcibly, and as his opinion is that of many others who have considered the question seriously it seems worth while quoting. He says:

"The text-books are worse than useless. They defeat the very object for which the Women's Christian Temperance Union labors. They entirely suppress the few beneficial effects of alcohol and unduly exaggerate the evil effects. All youths pass through an age of unbelief, of cynicism, of agnosticism. This age generally comes during the latter part of the High School course. When

* Physiological Aspects of the Liquor Problem. 2 Vols. Houghton, Mifflin & Co., New York and Boston.

they learn from authoritative sources of the benefits of alcohol, the reaction is marked. They immediately question the truth of the evils of alcohol and term what the books teach 'a lie.' Such has been my experience."

The conclusion of the committee as to the teaching of the physiology of alcohol in the public schools is as follows:

"It does not seem to this subcommittee desirable to attempt to give systematic instruction to all children in the primary schools on the subject of the action of alcohol or of alcoholic drinks. To older children, and especially those in the high schools, it does seem proper that instruction should be given as to the principal facts known about the use and effects of alcoholic drinks, the sociological and especially the ethical relations of the subject, the means which have been tried to prevent the evils resulting from alcoholism—and the results,—the object being to enable them to form an intelligent opinion upon the whole subject, especially to distinguish between mere assertions and scientific evidence."

This conclusion would it, seems to us, appeal to all those who are seriously interested as regards the instruction of youth in the liquor problem. The question of the evil of alcohol is rather sociological and ethical than physiological. To attempt to put it on a purely physiological basis is to invite the inevitable reaction against pseudoscience and debase and besmirch the dignity of true teaching.

There are many other interesting articles in this report. Professor Chittenden, for instance, discusses the influence of alcohol and alcoholic beverages on digestion and secretion. Dr. John S. Billings treats of the relations of the drink habit to insanity and furnishes data relating to the use of alcoholic drinks among brain-workers in the United States. Professor Atwater has a long and very valuable article on the nutritive value of alcohol. Some of his conclusions have already been the subject of no little discussion in the daily press. A very interesting, though brief communication, is that by Professor Bowditch, on the use of temperance drinks. Not a few of the tonics that even the "unco guid" and temperate may use with perfect propriety contain notable percentages of alcohol. As Professor Bowditch puts it, "It is clear that very large quantities of drinks, containing a greater proportion of alcohol than the ordinary wines and beers, are consumed among the most rigorous of total abstinence circles and one of the foremost advocates of total abstinence has permitted her picture to be used as an advertisement of one of the most alcoholic of these drinks."

It is to be hoped that this report with its thorough treatment of so important a question as the liquor problem will meet with the attention it deserves, and that the result of it will be an improvement in the present methods of teaching physiology in public schools, and, above all, that the precious information thus given will serve to put an end to the present ill-directed educational crusade on the liquor problem, which is at least as likely to do as much harm as good and probably has actually been an incitement to the trial of things condemned so severely, yet so commonly used, under the eyes of pupils, since the inevitable impression was sure to be created that if people around them took the risks they did in the matter of alcoholic drinks it must surely be because there was some wonderful attraction and some alluring satisfaction in them.

## THE MUTTERINGS OF THE ZEITGEIST.

REMOTE, indeed, are the regions into which the keen knife and the keener eye of the abdominal surgeon have not pierced. He has wrested every subtle secret from the coy and retiring appendix; he has shown that the possession of the gall-bladder is a display of unnecessary organic wealth; with deft and fateful hand he has drawn aside the veil which guarded the mysteries of the pancreas from the outer world, and sought to invade the forbidden precincts of digestion itself.

So great and so rapid was this progress that at one time it seemed inevitable that the unfortunate followers of these men would be afflicted with surgical ennui; be cast, nilly-willy, into a sort of surgical nirvana. However, the fog has again settled over the operating table; again, like the apostle, "we see as through a glass—darkly."

This state of things has arisen from the efforts of a few surgeons to take from the internist the majority of the cases of gastric disease. If we are to believe the words of the surgical Zeitgeist, the only sufferers under the new régime will be the manufacturers of dyspeptic tablets. This "time spirit" proclaims a relief of all kinds of perplexing dyspepsia by some simple, speedy and innocuous intervention. If the toiling and weary practitioner greets the announcement that he no longer will be called upon to prescribe pepsin, pancreatin and charcoal, with pleasure, what lusty cries of joy will rise from the public throat when it hears of its emancipation! The average

man does not like to take ichthyol for a stomach-ache till he smells to his friends and tastes to himself like an unseaworthy mossbunker fishing craft. When once educated he will easily prefer a little rift in his belly wall through which the ache may be reached. His stomach, where pleasure and pain sit cheek by jowl, is to the layman the most important and precious organ of the body. It has been pretty clearly demonstrated that most of the so-called *dyspepsia* is simply the clinical evidence of some remediable variation from the normal position, contour or size of the stomach or its parts.

Save in the rarely diagnosed condition of early neoplastic growth the mainstay of the surgical relief for the majority of these cases lies in the establishment of permanent fistulous openings. This is true, whether the condition is an inoperable carcinoma of the pylorus or any one of the many so-called simple diseases of the stomach. It is therefore easy to appreciate the importance, as well as the growing need, of some form of technic which, from a surgical standpoint, will most fully meet the requirements. That this standpoint is a broad one and difficult of fulfilment is attested by the great number of methods which have been devised. A modification of one of the most ingenious is presented in this issue (See page 483). There may be in this work the germs of a technic which will have world-wide application.

## ECHOES AND NEWS.

### NEW YORK.

**Entertainment for the Insane.**—Dr. E. C. Dent, Superintendent of the Manhattan State Hospital on Ward's Island, deserves great credit for the Labor Day program he prepared for the recreation of the unfortunates under his care. A printed schedule of the events had been prepared in detail and the patients as well as visitors enjoyed the afternoon's sports in the fullest degree. Such diversions for the disordered minds effect more good than barrels of drugs.

**Examination of Imported Foodstuffs.**—Acting on the instruction of the Secretary of the Treasury, and at the request of the Department of Agriculture, the Collector of the Port of New York had sample packages of a number of shipments of foods, including preserved fruits and vegetables, taken from the Public Stores. These will be sent to Washington for examination by the experts of the Department of Agriculture. The consignees of the shipments will be asked to call at the Custom House and make statements as to the purity of the goods imported. These statements will be forwarded with the goods. The first instance of the Government's refusal to admit to this country adulterated wines, under the Pure Food Act, took place last Saturday when entry was refused of a shipment of white wine from Bordeaux, France. Upon analysis this wine was found to contain salicylic acid.

**Asepsis at the Soda Fountain.**—The movement by the Board of Health to enforce more perfect cleanliness in barber shops is wholly commendable and no objection has been met except among the most ignorant. The same authority might be advantageously exercised over the popular soda fountains and its utensils. In one of the largest retail drug stores in New York, where the sale of soda water is made a specialty, dirty glasses removed from the counter, were placed beneath a faucet of running water and shaken about for a few seconds and then refilled with soda water for the next customer. Even in one's own home, where the danger of infection is, to a certain extent, a known quantity, one insists upon having the glasses that are removed from the dinner table at least washed with soap and hot water. How much more should similar cleanliness be observed in a place frequented by the general public. The simple immersion of the glasses in an antiseptic solution, which should not be scarce in a drug store, for five minutes and subsequent rinsing with plain water would remove all danger and would assure the customer that he was getting nothing with his soda that he had not paid for.

### PHILADELPHIA.

**Philadelphia Hospital.**—Dr. Fred. S. Johnson has been elected to the position of Assistant Chief Resident Physician. Dr. Johnson is a former interne of the institution and takes the place made vacant some months ago by the resignation of Dr. G. E. Pfahler.

**Additional Means to Prevent Spread of Smallpox.**—Announcement is made by the Department of Public Health that hereafter all the inmates of a house in which smallpox appears shall be taken to the Municipal Hospital with the patient. After twenty-four hours, during which they have undergone a disinfecting process, they will be returned to their home which in the meantime will have been thoroughly disinfected.

**New Medical Society Formed.**—Physicians of the Cumberland Valley, including Franklin, Cumberland, and Adams counties of Pennsylvania, and Washington county, Maryland, met at Mount Alto Park September 8, and organized the Cumberland Valley Medical Society. The program of the meeting included papers on tuberculosis, organization, professional sociability, and hemorrhage in typhoid.

**Death of First Woman Physician.**—Dr. Emily R. Robbins, who is said to have been the first woman medical practitioner in this country, died in this city August 31 aged seventy-one years. Dr. Robbins was born in Philadelphia, of Quaker parents, and graduated in 1857. She practised for a time at Fort Madison, Iowa, afterward marrying a classmate. At the beginning of the Rebellion Dr. Robbins and her husband came to Philadelphia, where, during the war, she devoted most of her time to the wounded soldiers who were brought to the various hospitals here.

**Typhoid and Filtered Water.**—The number of cases of typhoid fever for the week ending September 5 was considerably less than during the preceding week. The greatest number of new cases, however, developed in two wards, the Twenty-first and the Twenty-second, which are supplied with filtered water. Some of the people who are opposed to filtration have declared that filtered water does not prevent typhoid fever. Filtration Bureau officials declare that these deductions are unfounded. They are positive that if all the drinking water of the city

was filtered, typhoid would disappear. They explain present conditions on the assumption that the patients drank polluted water elsewhere. Arguments against filtration, they say, should not be made until all the water consumed in the city is filtered.

**Elaborate Nurse-supply System Planned.**—The daily papers give an outline of an elaborate system of nursing projected by the Philadelphia School for Nurses. The movement is ostensibly in affiliation with the National Red Cross Society but appears to be really a scheme of the above mentioned school. Briefly, the plan includes an institution, probably an office building, near the center of the city which will be the home of at least 100 nurses; these nurses will answer calls not only within but outside the city, even to the remotest sections of Pennsylvania, New Jersey, Delaware, and Maryland; a rule of the house will be to ask no questions about fees, as none will be required; those who can afford may contribute to the expenses of the institution; the service is to include only those patients who are suffering from contagious diseases. This movement apparently has great possibilities but its prospective benefits to patients are greatly lessened by the nature of the training supplied by this institution. The course of training, we are informed, extends over a period of ten weeks only. In remote districts such nurses may be better than none at all, but on the whole it does not seem that the movement is calculated to add laurels to the nursing profession. This institution is graduating hundreds of nurses, so-called. Their short training may be of value in their own homes but it would seem an ill-advised movement that sends them broadcast over the country.

**Municipal Hospital.**—Dr. J. F. Schamberg has resigned the position of Assistant Physician. Dr. W. M. Welch has been retired as physician-in-charge and made consulting physician. Dr. Welch has been in charge of the hospital for a period of thirty-three years. During this time over 24,000 patients were admitted to the institution, 8,000 of which had smallpox. The greatest epidemic of that disease occured during the winter of 1871-'72, when nearly 2,400 smallpox patients were cared for at the hospital. During the thirty-three years not one nurse or physician contracted smallpox while attending to their duties in the institution.

## CHICAGO.

**New Medical College.**—The opening exercises of the Dearborn Medical College, a new evening medical school, were held Sept. 1. The opening address was delivered by Judge R. S. Tuthill. The initial enrollment comprised 175 students. The President of the College is Dr. L. Blake Baldwin; the Secretary, Dr. James H. Wells. The College building is that formerly occupied by the Bennett Medical College, and later by the Chicago College of Pharmacy. A clinical building is now being erected.

**Taxation of Medical Colleges.**—A decision has been rendered by the Board of Review to the effect that medical colleges operated for profit shall be taxed on their equipments. Rush Medical College was taken under advisement; Hahnemann Medical College was not taxed; Chicago Homeopathic Hospital was taxed on $4,000, and the American College of Medicine and Surgery, Bennett Medical College and Jenner Medical College on $2,000 each.

**Preparations for a Health Exhibit.**—Commissioner of Health Reynolds has returned to Chicago after a trip to New York and the seashore. He has begun to make preparations for the Health Department's exhibit at the St. Louis Exposition. The work of the department will be shown in a manner similar to that which won for Chicago the gold medals at the Paris and Buffalo expositions.

**Improved Quality of Milk.**—Now that the quality of the milk is becoming more satisfactory, the energies of the Milk Bureau are being concentrated on the proper handling of milk. Cleanliness and the sterilization of bottles and utensils will be insisted upon even more strenuously than quality. The milk scouts are doing good work in this direction. Many of them are physicians and appreciate the importance of sterilizing utensils used in the handling of milk. The small stores near public schools are being carefully inspected. Milk dealers are complaining that the stores are not sanitary and are demanding that the sale of milk from them should be suppressed. The sale of milk and cream in stores has increased immensely since the inadequate "one-delivery-a-day plan" has been in vogue.

**Diphtheria.**—The attention of the Chief Inspector of the Health Department having been attracted to the unusual number of reports of diphtheria cases in the south end of Cheltenham, a house to house canvass of the locality was made by Medical Inspector, Dr. H. M. Richter, who found a number of unreported cases: one fatal case in which the family had been told by the attending physician that the disease was croup and not contagious. At the funeral there was a large crowd, many being children. The funeral was the probable cause of three other cases; also a midwife recovering from diphtheria, said to have been attending cases of the disease in the neighborhood, and delivered a woman next door immediately after her premises had been disinfected. The facts in the cases of the falsely certifying physician and of the midwife will be presented to the State Board of Health at its next meeting. In other parts of the city there is only the usual number of diphtheria cases; scarlet fever, measles, whooping-cough and typhoid fever are either stationary or decreasing in prevalence.

## GENERAL.

**Trichinosis in Homburg.**—In Homburg, Germany, and its vicinity two hundred persons are suffering from trichinosis.

**William II. as Surgeon.**—A piece of tree-bark about 18 to 20 inches long has recently been placed in a glass case in the Hohenzollern Museum in Berlin, which bears this inscription: "Tree-bark with which His Majesty, the Emperor, improvised a temporary splint for the arm of Her Majesty, the Empress, at the time of her accident in the Grünewald, March 27, 1903."

**Another Medical Journal Passes Away.**—With the issue of the August number, the *Quarterly Medical Journal for Yorkshire* closes its existence. Founded in 1892 as the *Sheffield Medical Journal*, it soon enlarged its sphere of action and assumed its later title. "During the eleven years of publication it has been the aim," so states its obituary, "of those responsible for it to maintain a high standard of medical literature." The editorial staff returns thanks to the public, but no definite reason is stated for its discontinuance.

**Tuberculosis and Cigars.**—The investigations of Perserico in Italy have shown that the stumps of cigars smoked by tuberculous subjects and kept dry for a period of two to three weeks are capable of producing tuberculosis in guinea-pigs. As an important result of these findings, the Cuban authorities now require that, in all cigar factories, a sponge shall be used in finishing off the ends of cigars instead of their being moistened with the lips of the operator as formerly.

**Typhoid Epidemic at Metz.**—There is an epidemic of typhoid fever at Metz, due to bad water, and this is the occasion for shutting off the city supply. The irri-

tation of the local authorities is due to the despatch of the Emperor William to Prince Hohenlohe-Langenburg, the Viceroy of Alsace-Lorraine, in which the Kaiser says the state of affairs, which threatens the health of the garrison, is due solely to the city administration of Metz, "which is absolutely unable to decide what steps to take with regard to its water supply. Since the time of the Romans the mountain springs at Gorze have supplied Metz with its water. A water famine prevails in Metz, and the hotels are unable to satisfy their wants."

**Mont Blanc Place for Consumptives.**—Prominent French physicians are now turning their attention to Mont Blanc and the Mer de Glace as possible sites for consumptive sanatoriums. Dr. Kass, director of the Paris Municipal Sanatorium, took a number of pauper consumptives to the Mont Blanc Observatory this week to study the effects produced on them during the month. Dr. Bayeux, of the Saint-Lazare Infirmary, is carrying out similar investigations on the Mer de Glace and has expressed the opinion that the disease can be coped with and perhaps cured by proper treatment there.

**Pathology as Seen in Works of Art.**—Dr. Paul Richter, the recently-appointed professor of anatomy in the Paris Ecole des Beaux-Arts, was formerly an assistant of the eminent specialist in nervous disorders, Professor Charcot, at the Salpêtrière. For him he made a number of sketches demonstrating hysterical symptoms. While doing this work he was led to adopt the maxim that there can be no perfect beauty without perfect health. He noted pathological features in many well-known works of art, and concluded that faulty models were responsible. He accordingly advises his pupils to avoid the usual atelier models, and seek for the lines of human beauty among the acrobats in the circus, the blacksmiths, and the partially nude laborers at the docks and in the fields. "Beauty in action" is his motto.

**Longevity of Ministers.**—It is the universal testimony that clergymen reach the highest age, being close run by gardeners and vine dressers. Ordinary agricultural laborers, although their occupation is so largely in the open air, are not conspicuous as long livers, except in France, Sweden, and England. People working with wood are longer lived than those whose occupations are with metals, and both attain a higher age than textile workers and workers in chemical industries. The shortest lived people are miners, except in England, where the superior mining regulations and admirable sanitary arrangements have a beneficial effect. In England and Norway sailors and fishermen live to a far greater age than in Germany and France.

**The Bacillus in War.**—The Macedonian revolutionists, it is reported, threaten, in case they cannot bring about a war between Turkey and Bulgaria, or induce European intervention, to decimate the populations of the Macedonian cities controlled by the Turks by poisoning the wells with the bacilli of the plague. This is really a formidable threat, easy of execution, terrible in its consequences, and picturesquely barbarous. The plague bacilli can be put up in soluble capsules of small size, and might be dropped into wells without attracting any attention. From the point of view of the advantage of the human race it is not certain that the depopulation of this part of the world by pathogenic bacteria would be an unmixed misfortune, but this consideration in no wise mitigates the fiendishness of the crime of planting the seeds of a subtle and uncontrollable infection in soil where it would linger for years, with almost inevitably fatal consequences to all.

**Alarming Increase of Lunacy.**—Dr. A. B. Hays, superintendent of the Louisiana State Insane Asylum at Jackson, La., believes in adopting the radical measures to prevent insanity and points out that unless this be done the burden of caring for the insane will soon be too heavy for the sane to bear. In Louisiana insanity is increasing at the rate of more than 10 per cent. a year, or five times as fast as the population. When he took charge of the State asylum in 1896 there were 850 insane persons; there are now 1,550, an increase of 80 per cent. in seven years, while the population has grown only 15 per cent. Dr. Hays is in favor of radical legislation. He thinks the Louisiana legislature did well at the last session in prohibiting consanguineous marriage, to which he attributes a great deal of the insanity of to-day. The legislation against the sale of cocaine was also a move in the right direction, he thinks, and especially to the benefit of the negro race, who, under the influence of the drug, are driven mad by hundreds. The exhilarating or soothing effects of cocaine have brought other drugs into use among the negroes. Morphine, digitalis and half a dozen other poisons are slowly creeping into favor with them.

**Deterioration in British Lower Classes.**—The English Government has appointed a commission to inquire into the alleged physical deterioration of the lower classes in the United Kingdom. The clerk of the Privy Council is chairman, assisted by the former head of the Army Gymnastic School, the inspector of reformatories, the chief of the Navy Recruiting Service, statisticians, and others. The subject was brought up in the House of Commons by Sir William R. Anson, Parliamentary Secretary to the Board of Education, who declared that 60,000 children now attending London schools were physically unfit for instruction. The Director-General of the Army Medical Service reports that one man in every three offered as recruits had to be rejected. The appointment of the commission is hailed with approval. The *Daily Chronicle* says: "If the people as a whole are deteriorating, we must change our ways or give up the national struggle as a mistake. The creation and preservation of a fine stock of mankind is the first, perhaps the only reason for national existence, and if the mass of the people is going down hill in physique we may be quite sure it is going down hill in character and intellect as well."

**"Cuban Plague."**—During the past week much publicity has been given to a spurious report that a severe epidemic of yellow fever or some equally fatal infection had broken out in eastern Cuba and that its presence was being denied for political or commercial reasons. Unfortunately several of the more reliable representatives of the daily press gave prominence to the subject. The following denials from the Marine Hospital Service and from Dr. Guiteras make it certain that there is no yellow fever and suggest the inference that a few deaths from pernicious malaria have given the only foundation for the scare. Dr. Walter Wyman, of the Marine Hospital Service, which is maintaining a vigilant surveillance of the health of Cuba, states that no advices have been received from his agents diagnosing any sickness whatsoever as yellow fever. This statement is supported by a despatch from Minister Squiers at Havana, who says that the island has a clean bill of health so far as that dreaded scourge is concerned. His exact words are: "The whole island is free from smallpox and yellow fever." He adds: "In many of the provinces the death-rate has been abnormally low, owing to the improved methods of sanitation." Dr. Guiteras, who went to the Province of Santiago to investigate the rumors of plague there, telegraphs that there is no yellow or black fever or other epidemic at Santiago or Daiquiri. At Daiquiri there are some serious cases of malarial fever.

**Child Labor in New Jersey.**—On September 1, the new law concerning child labor in this State took

effect. It provides that no boy or girl under fourteen years of age shall be permitted to labor in any factory or workshop in any capacity whatsoever. The age limit is thus raised two years, the former act making it twelve years for boys and fourteen for girls. Last winter the legislature passed an act placing in the hands of Governor Murphy authority to enforce the law. The Governor has taken a decided stand in his public messages and speeches, and it is to be hoped that the present effort will be attended with success. At any rate it will give the public an idea as to the value of promises on the part of State authorities. The glass blowers of South Jersey, among whom child labor is at a premium, have threatened to contest the constitutionality of the new law, because of a silly provision in the act that it should take effect on September 1, without specifying whether it should be this September or some other September. While the failure to prescribe a definite date was either a stupid blunder of the legislature or a deliberate attempt to palm off an act that would not hold water, the department has been advised by the Attorney-General, it is understood, that the omission will in nowise affect the validity of the act. At any rate, the department has asserted its intention to insist upon compliance with the law and to prosecute all manufacturers who employ children under the prescribed ages. Since the technical objections to the act do not go to the merits of the measure, the factory inspector has taken the stand that all offenders should be prosecuted to the full extent of the law and this he says he is prepared to do.

**Leper Colony in Porto Rico.**—A bad state of affairs has been discovered on Cabras Island, on which the leper colony of Porto Rnco is located, at the entrance to San Juan harbor. As a result the Executive Council of Porto Rico recently held a special session, by request of Acting Governor Hartzell, and has ordered a thorough investigation. It has been believed, until this discovery, that the leper colony has been conducted in a manner most creditable to all concerned. The insular government has been expending about $10,000 a year for its maintenance. Dr. Goenaga, acting director, found dogs, goats, chickens, rabbits, and pigs herded with the lepers, the chickens nesting in the unclean beds. The patients were in a filthy condition, with no bathing facilities and most of them clad in rags. The food supplies stood about exposed to corruption. In these surroundings he found two "patients," one an old man, and the other younger, who were not afflicted with leprosy. The old man was committed years ago as a leper, thus being consigned to slow and awful death, and the younger man was sent to the colony later. These men will be removed this week and especially quarantined in a building now being constructed, for a sufficient time to make their release safe. There are now in the Cabras Island colony twenty-three lepers, and at least as many more, it is believed, are scattered through Porto Rico. The Superior Board of Health, within whose province is the determination of this disease, has had many difficulties to contend with in its endeavor to deliver to the colony the balance of those afflicted and at large on the island. One of the difficulties is that of transportation after discovery, the common carriers absolutely refusing to bring the lepers from the surrounding country. The board is now trying to solve the problem by arranging for special oxcart transportation at government expense. It is hoped that within a year all the lepers of Porto Rico will be segregated at the colony.

**Obituary.**—Dr. James Hibbard, aged eighty-seven, died in Richmond, Ind., September 8. He was an ex-President of the American Medical Association.

Report of the death at Harrenalb, in the Black Forest of Würtemberg, Germany, of Dr. Joseph Schnetter, one of the founders of the German Hospital and Dispensary of New York, and for forty years an active practising physician in this city, has just reached his friends in New York through his late residence in the city of Karlsruhe, Germany. He was eighty-two years of age. Dr. Schnetter was born at Gerolzhoven, Bavaria, and was graduated from the University at Würtemberg. Jealousies on the part of his fellow-students caused him to leave the university, where he was offered a professorship, and to come to America in 1849. He settled in New York. He became connected with many charitable institutions, among them being the German Hospital and Dispensary. In 1889 illness caused him to give up his practice.

Dr. Henry De Haven Cameron, late surgeon of Troop C, N.G.N.Y., died in Pony, Mont., on Friday, after a long illness. He was born in Brooklyn thirty-seven years ago and was a graduate of the New York College of Physicians and Surgeons. For a time he was an interne in the New York and Chambers Street hospitals, and later served two years in the Methodist Episcopal Hospital in Brooklyn, when he became well known professionally even before he commenced private practice. He was one of the organizers of Troop C in 1890, and was first appointed assistant surgeon, in which capacity he served several years. He returned from India, where he was traveling, at the outbreak of the Spanish war, and served with his troop through the Porto Rico campaign. When the troop was mustered out he was promoted to the rank of surgeon which he held to the time of his death. As a mark of appreciation of his services, he was presented with a sword and full riding outfit by the officers and privates of his troop. He was well known in Brooklyn and New York in the National Guard and in the medical profession. He was for years identified with the Methodist Episcopal and Norwegian hospitals. Owing to ill health, he was compelled to go to the far West, from which he returned improved, but still suffering from the conditions that finally caused his death.

Dr. Luis P. Walton, of New York, died suddenly September 8 at the Bath Club, in London. He had been swimming and on coming out of the water complained of feeling ill, and lay down to rest a while. He died within an hour of heart disease. Dr. Walton was a son of Dr. Henry C. Walton, an English practitioner, who came to New York in 1850. Dr. Walton was born in Liverpool just previous to the time of his father's removal to this country. He studied in the schools of New York, and, taking the medical course at the College of Physicians and Surgeons, was graduated in 1870. He spent several years in the college dispensary, and then began general practice, in which he was very successful.

## CORRESPONDENCE.

### BOTHRIOCEPHALUS LATUS.

THE following letter was forwarded to the MEDICAL NEWS by Dr. Berkeley, and is of interest in connection with his paper published in our issue of August 1.—[ED.

W. N. BERKELEY, M.D.:

DEAR DOCTOR—In answer to the request in your favor of August 23, I have obtained the following facts from

the patient and my own memory and books, in relation to the case of *Bothriocephalus latus* spoken of in my letter.

Nearly nine years ago (Sept. 4, 1894) the mother of the young lady who suffered with it came to my office, bringing some segments of the worm to ascertain what they were, stating that her daughter had passed them with her feces. Upon examination, I told her they were from a tapeworm, and that I would see the patient taking proper medicine and instructing her how to use it. A few days after I did so, and found she had passed other segments, which I saw and noticed that they were endowed with motion similar to the movements of the measuring worm. She stated that she had been passing them for about a week. She complained in no way except from an irritability of the nervous system, and after knowing her condition, with intense disgust at the idea rather than discomfort from it. A few days thereafter her mother brought to the office the whole worm with head, which had been passed by her, and which I still have. It was, I think, about 19 feet long (have not taken it from the bottle to measure now, for fear of damaging it). Segments very narrow and short, being about five-eighths of an inch long and one-half of an inch wide, then tapering in width to one-fourth of an inch, still being five-eighths of an inch long; the openings being all along the same side. I had administered pelletierine, with castor oil following, of course restricting diet. The patient does not have the least idea where she obtained it. Was in Europe several years before, and a tour to Egypt and Holy Land was taken several years after she passed it. She cannot tell how long she was afflicted with it, but I do not suppose she obtained it in Europe, being so long before she passed any segments.

I find there is a constriction of two or three segments in one portion of the worm, they assuming the form of those near the terminal end, and again becoming wider, assuming the shape previous to the constriction.

Horace M. Bellows, M.D.

Huntington Valley, Pa., Aug. 29, 1903.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

London, August 29.

THE DULL SEASON—DEATH OF A PROMINENT SANITARIAN—THE "SWEDISH CURE."

We are at the height, or rather the depth, of the dull season, and in the Temples of Medical Science in Harley street and Grosvenor Square the oracles are dumb, or are replaced by understudies. This is the time when the young Lazarus of medicine picks up the crumbs that fall from the rich man's table. But everyone else is away; the medical schools are in recess, and silence reigns in the debating rooms of the Societies. The medical world should therefore be happy, for at present it has no history.

There is, however, one most experienced operator, not strictly belonging to the profession, though very intimately associated therewith, who never takes a holiday. In season and out of season he is at work, for, as Robert Burns says,

> Folks maun do something for their bread
> And sae maun Death.

He has just struck down one of our leading sanitarians in the person of Professor W. H. Corfield, of University College, London. After a brilliant career at Oxford he studied medicine in London and on the Continent. Early in the seventies he was appointed professor of hygiene in University College, being the first holder of such an appointment in London. To him, too, the first laboratory of hygiene founded in London, that at University College, mainly owes its existence. He took a leading part in organizing the International Congress of Hygiene and Demography held here in 1891. He was a member of many foreign scientific societies, and was the author of several books dealing with matters within his special province. Among them may be mentioned a *Résumé of the History of Hygiene; Dwelling Houses: Their Sanitary Construction and Arrangement; Disease and Defective House Sanitation* (which was translated into French, Italian and Hungarian); and *The Etiology of Typhoid Fever and Its Prevention.* Two or three years ago he was appointed sanitary adviser to His Majesty's Office of Works. He had also a very lucrative practice as a consulting sanitary expert. He was an eager collector of old books, though he seemed, like most bibliomaniacs, to care more for the rarity and especially the bindings of his books, than for their literary quality. Still, he did know something of the contents of his treasures. He had a remarkable collection of woodcuts of Thomas Bewick, and a considerable number of choice prints. The story of his last illness presents some remarkable features. Two or three years ago he lost appetite and digestion; his frame, always small and spare, wasted to a degree recalling Falstaff's description of Justice Shallow ("I do remember him at Clement's Inn, like a man made after supper of a cheese paring"); his face had an earthy look—in short, he had all the appearance of a man suffering from advanced malignant disease. The seat of the pain and other symptoms suggested cancer of the stomach. All his friends thought he was dying. Suddenly a startling change took place. He was able to eat beefsteak without discomfort; his shrunken form filled out and his face recovered the ruddiness of health. He attributed his cure—for such it seemed to be—to a peculiar form of Swedish treatment consisting, as far as I could make out, in manipulations directed to stimulate the nerve ends over the area of discomfort. He was enthusiastic about the treatment, and must have been an excellent advertisement for the healer who had wrought such a wonder in him. But, alas! the vanity of human things is as strikingly exemplified in quackery which has faith on its side as in orthodox medicine which leans on the broken reed of reason. It became painfully clear that the apparent "Cure" was but a temporary response to stimulation. Corfield did not, however, lose faith in vibration massage. Hope springs eternal in the human breast and he went to Sweden in order, I suppose, that he might get the treatment at the fountain head. He was looking about for some other shrine of healing when death brought his quest to a sudden end. He had not completed his sixtieth year.

The "Swedish treatment" is very fashionable here at present, and many professors of the art are earning incomes that make even successful physicians green with envy. The profession in this country, which is fanatically conservative, has always looked more or less askance at massage, and as far as the general body is concerned, it is only now beginning to realize that it has any value. Hence it comes about that this method of treatment is to a large extent in the hands of quacks, and is therefore looked upon by sticklers for professional purity as an unclean thing. This is regrettable from every point of view. There is much, as Dr. Wharton Hood has shown, to be learned from bone-setters, and the same may be said of the Swedish manipulators, *Fas est et ab hoste doceri.* The profession should imitate the example of Molière and take what rightfully belongs to it wherever it may be found. The doctors will be driven before long to recognize the logic of facts, but by that time their chance of captur-

ing the treatment and giving it the consecration of orthodoxy will be well-nigh gone. Already some of the leaders of the profession meet bonesetters and Swedish curers on the sly. They would of course say that they superintend the treatment, but the fact is that in the alternative presented to them of losing their patients or meeting the illegitimate practitioner, they prefer the latter course. The fashionable quacks are in a position to dictate their terms. One noted "Professor" who requires a dozen "operating rooms" and a large staff of assistants to meet the exigencies of his practice, has among his patients the very flower of English society, including the Royal family. It may be said that these people, being silly, are the natural prey of quacks, but among the clients of the masseur and the bonesetter are judges, generals, ecclesiastical dignitaries—in a word, the heads of every profession but the medical. And, as has been seen, even the bigwigs of medicine, like Professor Corfield, when in the grip of *ineluctabile fatum*, seek help from quackery.

## SOCIETY PROCEEDINGS.

### BRITISH MEDICAL ASSOCIATION.

*Seventy-first Annual Meeting, Held in Swansea, July 28, 29, 30 and 31, 1903.*

(Continued from Page 432.)

**Pathology and Treatment of Chorea.**—Dr. D. B. Lees said: "Our subject to-day is the pathology and treatment of that common disease of childhood which is so inadequately and incorrectly described by the name 'Chorea.' Inadequately, for there is much more than abnormal muscular movement in this malady. Incorrectly, for whatever else a choreic patient may do, there is a total absence of any rhythmic movement which might fairly be described as 'dancing.' It is most unfortunate that the name should wholly misrepresent the disease. Perhaps, when the pathology is completely understood, a better name may be invented. Meantime let us define our subject by excluding all varieties of hysteria, all forms of habit-spasm, and all irregularities of movement resulting from gross cerebral lesions, such as athetosis and 'post-hemiplegic chorea.' And in this section we neglect the rarer chorea of adults and of old age, and concern ourselves only with the so-called 'chorea' of childhood.

"The most obvious fact in chorea is disorderly muscular movement, spasmodic, clonic, irregular, involuntary, with imperfect control and coordination. If we observe carefully the distribution of these involuntary movements, we find that it is precisely the muscles over which we have most voluntary power that are most affected in chorea—the muscles of the face, those of the tongue, and those of the hands and arms. These are the muscles which specially express emotion—by grimace, speech, and the movements of the hands and arms which naturally accompany eloquent or excited speech, especially in the more emotional races. It is precisely these muscles which are most affected in chorea: the face, tongue, and hands are much more implicated than the proximal parts of the upper limbs, the upper limbs more than the lower, and the lower limbs more than the muscles of the trunk.

"Respiration, over which we have a real though limited control, is affected much more than the action of the heart, over which we have no voluntary power whatever. The heart's action may, indeed, be irregular in chorea, but it is much less so than the respiration, and the heart often works steadily enough while the breathing is quite irregular. Choreic movements are often more pronounced on one side of the body than on the other, and in slight cases they may be limited to the limbs of one side. Choreic movements cease when the patient falls asleep, and recur when he wakes.

"These facts, taken together, indicate unmistakably a disorder of the brain, and specially of the motor centers. In the Rolandic area of the cortex much space is allotted to the movements which are specially under voluntary direction and control—to the face, hand, and arm—less to the lower limbs in proportion to their size, and comparatively little to the muscles of the back and of the abdomen. The relative affection of the different muscular movements in chorea corresponds to the cortex arrangement.

"It is clear that in chorea these centers are in an abnormally excited state, for if you ask a choreic child a question, its hands will often reply before its month. Place the child at rest, with its arms and hands outstretched on the bed, and wait for a quiet interval when the choreic movements have ceased, or are at all events much diminished. Then ask the child a question, however simple, its name, or the number and names of its brothers and sisters. Usually the choreic movements recur at once in the hands, often before the reply is uttered, or if they have not previously ceased, they become very rapidly much more violent. It seems that the outgoing impulse to the speech center finds the adjoining centres of the motor area abnormally excitable, and overflows into them. Sometimes the choreic movements follow so quickly after the question that it almost seems as if the ingoing auditory impulse had reached them directly.

"Similarly, if the child squeezes an object firmly with one hand the other hand usually becomes more decidedly choreic. In a case of hemichorea, a strong squeeze with the unaffected hand brings out additional movements in the choreic hand, while a squeeze with the affected hand produces little or no effect on the other. This seems to indicate clearly that the hand center in the cortex on the one side is more excitable than that on the other.

"The motor centers are not only irritable, they are also weak. This weakness may be obvious from the first, but it is apt to become greater as the irritability subsides. The grasp is feeble, and the weakness of the whole upper limb may be so great as to deserve the name of paresis. When the hands and arms are outstretched, the child standing or sitting, there is usually a slight flexion of the wrist, apparently due to loss of tone of the special extensors, and the voluntary extensor effort of he common extensor of the fingers slightly overextends the first phalanges. It may be impossible for the patient to walk, to stand, to rise from the recumbent position, almost impossible even for him to lift one leg over the other.

"It is clear that in chorea much more than the Rolandic area of the cortex is affected, and it is probable that the whole brain suffers more or less. Is the cord affected also? If so, its affection is overshadowed by that of the brain, as in tuberculous meningitis. But one phenomenon is observed which may indicate an extra irritability of the spinal ganglion cells—an increase in the briskness of the knee-jerks and a tendency to a prolonged extension of the knee when the patellar tendon is struck. Possibly also the atonic condition of the wrist extensors may be of spinal origin.

"Are the peripheral nerves affected? Choreic children sometimes complain of flying pains in the limbs, away from the joints, which may possibly be neuritic. In some cases of chorea the knee-jerks cannot be obtained, though it is not certain that this is really a symptom of the disease, or how, if a symptom, it is produced. And the occasional occurrence of slight optic neuritis, mentioned by Sir William Gowers, must

also be remembered. It may be added that choreic children often suffer from constipation; the cause of this is uncertain.

"In chorea, then, there seems to be a disorder of the whole cerebral cortex, probably of the whole brain, possibly of the nervous system in general, sufficient to produce very definite symptoms, and often lasting for a long time. Yet the disorder is not a destructive one; it usually ends in complete recovery. The pathological changes are, therefore, if organic, of slight intensity, and it seems probable that the morbid state may be largely due to a toxemia. Yet the fact that the symptoms may be very definitely localized suggests that the cause cannot be simply a toxemia; there must be something focal as well. The changes found post mortem in the brains of the few cases which end fatally have been mainly confined to the vascular system—hyperemia, dilatation of vessels, perivascular leucocytes, thromboses, and slight hemorrhages. Alterations in the nerve cells have also been found by several observers. A recent investigation of two fatal cases by modern histological methods by Dr. Reichardt, of Chemnitz, showed small hemorrhages, irregularly scattered, with collections of leucocytes, chiefly mononuclear, and dilatation of vessels, with perivascular small-celled infiltration, in many parts of the brain, in varying amount. No changes were detected in the ganglion cells, but there were areas of fatty degeneration of nerve fibers; in the spinal cord the parts most affected were the root fibers and the anterior and lateral horns, and the posterior columns—the anterior and lateral tracts were free. Cultures from the fluid of the cerebral ventricles of the first case gave no result, but '*Staphylococcus aureus*' was obtained from the heart blood. In the second case there were '*Streptococci*' in the cardiac valves, and a few colonies of '*Staphylococcus albus*' were obtained from the brain.

"If we look for clinical evidence of a morbid blood-state in chorea, we find that it is frequently accompanied by manifestations of the toxemia which we call 'rheumatism.' Any of the ordinary rheumatic phenomena in a child may accompany chorea—tonsillitis, arthritis, erythema, nodules, cardiac dilatation, endocarditis, pericarditis, pleurisy. The most frequent of these is cardiac dilatation, for in chorea, as in rheumatism, the left ventricle is almost always too large, the left border of the heart extending beyond the left nipple line, often as much as one fingerbreadth, and the first sound being feeble. The next commonest is a systolic apex murmur; whether this is always due to valvulitis is uncertain, but in many cases it is so undoubtedly. In almost all fatal cases of chorea recent vegetations are found on the mitral valve. A fairly frequent evidence of rheumatism is the rheumatic nodule, single or multiple. The neighborhood of the various joints, also the tendons of the hands and feet, the occiput, and the vertebral spinous processes ought to be carefully examined for nodules in all cases of chorea. The other manifestations of rheumatism must also be borne in mind, and special care should be taken not to overlook a pericardial rub.

"I draw special attention to the fact that chorea is often the first of a series of rheumatic attacks. If this be ignored, and the relationship of the two diseases be based simply on the precedence of rheumatism, the connection of the two will inevitably be understated. It occurred to me that it would be worth while to investigate carefully the amount of subsequent rheumatism occurring within a few years after an attack of chorea in children who had had no rheumatism previously. Dr. Batten was good enough to investigate this point in the out-patient department of the Hospital for Sick Children."

"He found in 115 cases of chorea that whereas the percentage of previous rheumatism was stated to be only 32.2 per cent., three years later so many of them had subsequently suffered from rheumatism that the percentage rose to 43.5, and three years later still it had risen to 53.2, so that the lapse of six years had increased the percentage by 21 per cent. And this is below the truth, for after the lapse of six years as many as 38 of the 115 children could not be investigated. If the same proportion of these missing ones had become rheumatic, the percentage would be increased, not by 21, but by 28 per cent. This added to the cases of 'previous' rheumatism would give a total percentage of 60 per cent.

"The clinical evidence is in reality very strong, and we turn with interest to the excellent work of Drs. Poynton and Paine on the bacteriology of rheumatism to learn whether they can throw light on the pathology of chorea. I need not remind you that these observers, by a series of investigations, have isolated from the tissues in cases of fatal rheumatism, and also from the blood of rheumatic patients during life, a diplococcus which they have been able to cultivate, and which when injected intravenously into rabbits, has produced in them all the symptoms of a violent rheumatism in a child, and that a recent subcutaneous rheumatic nodule, excised with aseptic precautions two hours after death, at once immersed in a suitable medium and cultivated for forty-eight hours in an incubator, was found to contain an exuberant growth of this organism without the presence of any other. In my judgment these results are decisive.

"Accepting then the fact as now demonstrated that rheumatism is a disease caused by a diplococcus, and remembering its close clinical connection with chorea, we ask with interest whether this diplococcus is also responsible for the production of chorea. The evidence on this point is as yet scanty, but it is extremely suggestive. One of the rabbits injected with a culture of this diplococcus obtained by incubating pericardial fluid from a fatal case of rheumatism, developed symptoms remarkably resembling chorea in a child—clonic irregular involuntary spasmodic muscular movements, especially of the forelimbs and of the face, with a condition of 'nervousness' such that it started at any sudden noise. This rabbit was killed, and diplococci were found in the lymphatic sheath of the vessels in the pia mater and in the endothelial cells of the blood capillaries penetrating the cortex of the brain.

"A second fact is this. Dr. Poynton cut sections of the brain of a fatal case of chorea which had been preserved for three years, and found diplococci in the cortex itself, also in profusion in the mitral valve. These, however, were not cultivated, so that it is not proved that these were the rheumatic diplococci. Yet if we take these two facts together, and remember that Dana, Apert, Wassermann, and others have isolated a diplococcus from the brain in fatal cases of chorea, it becomes more than probable that before long the demonstration will be made complete. Fatal cases of chorea are happily uncommon, and it will require some time before the point can be proved.

"But if it has been shown that these diplococci are almost always found in the heart in fatal cases of rheumatism, and if they have actually been found in the blood during life, it seems certain that they must often reach the cerebral circulation. If their presence in the pial vessels and the cortex is the cause of chorea, we must look upon this disease as a microbic invasion of the brain, as in tuberculous meningitis. Why the result is so different in these two diseases must depend upon a difference in the virulence of the microbe, and the different measure of resistance on the part of

the phagocytes and other defensive mechanisms. In this respect some recent observations by Drs. Poynton and Paine are of interest. They found that in the arthritis of rheumatism the fluid effusion is usually sterile; that the diplococci are present in the synovial membrane of the inflamed rheumatic joint, but that they are there seized upon by the phagocytic cells, and that the diplococci contained in these cells are so much devitalized that they can no longer be cultivated.

"Why the rheumatic diplococci should cause chorea in children and not in adults; why some rheumatic children should become choreic and others not: and why girls should be choreic three times as frequently as boys, must depend upon differences of individual power of resistance.

"Are we then to say that chorea is 'cerebral rheumatism?' Yes, if we add 'in the great majority of cases.' But we must not make the statement absolutely, for other microbes and other toxins may perhaps affect the cortical cells in the same way as the rheumatic diplococci and their toxin, just as the *Bacillus coli* and the *Bacillus enteritidis* of Gärtner may produce a continued fever resembling that caused by the typhoid bacillus; and, to say nothing of 'senile chorea,' the disease known as Huntington's chorea is found to be caused by multiple organic sclerotic changes in the cortex. It is even possible that the sudden emotional disturbance caused by fright may in some way disturb the nutrition of the cortical cells in a susceptible brain in a way similar to the altered nutrition caused by the rheumatic toxin. Sir William Gowers reminds us that throughout the animal kingdom the emotion of alarm has a direct effect on the motor centres essential to the safety of the animal alarmed. Cases of chorea really caused by fright in the absence of rheumatism are rare, but they probably exist; the difficulty is to prove the absence of rheumatism.

"I desire then to maintain that every case of chorea, however mild, ought to be looked upon as presumably rheumatic. And when we remember the danger of untreated rheumatism in a child, and the heart disease which it so frequently causes, we see how great an injury one may do to a child by neglecting a slight chorea. Many a mitral stenosis in later life, with its distressful years and its premature death, might have been averted if the practitioner who attended the case of slight chorea in childhood had treated it vigorously as rheumatic.

"If, then, in the majority of cases chorea means a brain infected with rheumatic diplococci, surely the treatment which cures rheumatism ought to cure chorea. Yet it is not the general experience that much has been effected in this way. May not this be because the doses given have been too small? If one wishes to cure a cerebral syphilis, large doses of iodide must be employed. Acting on this idea, I have lately given to cases of acute chorea large and frequent doses of sodium salicylate, to which invariably has been added twice the amount of sodium bicarbonate. This addition of alkali I think of great importance, from more than one point of view. In a considerable number of cases this treatment has produced a very rapid improvement. The plan is certainly deserving of further trial in acute chorea. Success seems to depend upon the amount given daily, a further improvement sometimes following each increase of the dose. That the improvement is not due merely to the rest in bed, nursing, and feeding has been proved in some cases by allowing three or four days to elapse before administering medicine. Some cases grow worse if left untreated, others improve slightly.

"The dose of sodium salicylate for a child of six to ten years should be at first 10 gr., with 20 gr. of sodium bicarbonate. After two or three days the quantities should be increased to 15 gr. and 30 gr., respectively. After two or three days more they may, if necessary, be increased to 20 gr. to 40 gr. These doses should be given every two hours during the day, and every three hours during the night, ten doses in the twenty-four hours. Thus the total amount of salicylate given at first is 100 gr. daily, increased to 150 gr., and finally to 200 gr.

"A careful watch must, of course, be kept for any symptoms of salicylate poisoning, and especially for a peculiar deep inspiration simulating the 'air-hunger' of diabetes. If this occurs the medicine must be immediately given up, for it is a sign of danger. It is, however, a rare phenomenon. There is some reason for thinking that it is really an acid poisoning. The similar 'air-hunger' of commencing diabetic coma may sometimes be arrested by large and frequent doses of alkalies, and the only fatal case of salicylic air-hunger that has come under my own observation had taken the salicylate without any additional alkali. Air-hunger began to show itself in one case which I treated with aspirin, instead of salicylate, without alkalies, and disappeared when the drug was omitted. It seems to me very important that each dose of salicylate should be accompanied by twice as much bicarbonate.

"The unpleasant symptoms sometimes caused by salicylates in adults, the deafness and noises in the ears, the headache, the mental symptoms and delirium, are exceedingly rare in childhood. Occasionally vomiting is troublesome, but it may usually be overcome by suspending the treatment for a few hours and then beginning again with a smaller dose, which should be gradually increased. Pulse failure occurring during the employment of salicylates, both in children and in adults, is generally not due to the remedy, but is caused by an acute rheumatic dilatation of the left ventricle—a common, but usually overlooked, phenomenon in rheumatism. Careful observation of the position of the border of the left ventricle, as ascertained by accurate light percussion, should be made daily. As to any general 'depression' from the salicylate, in children it is usually quite absent; indeed, it has been remarkable how much brighter and more lively the patients have become during the treatment. It should be added that the large doses of bicarbonate do not impair appetite or disturb digestion in rheumatic children, and that, in spite of them, the urine often remains acid for a considerable time. Albuminuria is not caused by the treatment above advised.

"Every choreic child should, I think, be kept for a time completely at rest in bed, however mild the chorea may be. If there is much tendency to excitement, restlessness, or emotional attacks, complete isolation is very helpful. A cot with padded sides is necessary in severe cases, and the most careful and efficient nursing is essential. It may be needful to give in such cases hypnotic drugs, as chloralamide, chloral, or bromide, the first night or two, to secure sleep, but in many cases these can be avoided if large doses of salicylate and bicarbonate are used. The diet at first should be of milk only."

**Salicylates in Chorea.**—Dr. Henry Ashby said: "I agree with Dr. Lees that the rheumatic toxin is the most important factor in the production of chorea, but I am not inclined to the belief that all cases of chorea are rheumatic. Chorea is exceedingly common in overgrown, anemic girls in whom there is no evidence of rheumatism or of heart disease, and I do not think that in this class of cases salicylates are of much use. The bacteriological evidence is most important and ultimately the question of the rheumatic origin of all cases of chorea will be finally settled by this means. The observations of Dr. Lees on the treatment of chorea by large doses of salicylates are very important. I confess I am some-

what frightened of such doses as he recommends. I am inclined to think that more moderate doses of some 40 to 60 gr. daily are likely to do all the larger doses will, and with less risk. Antipyrin in moderate doses is certainly useful in acute cases. Arsenic is of doubtful value and in large doses almost certainly harmful. After all, rest in bed and careful dieting are the most important essentials in the treatment of chorea."

**Serious Cardiac Lesions as a Sequel of Chorea.**—Dr. Theodore Fisher said: "The few remarks which it has occurred to me may be worthy of bringing forward in connection with this discussion, deal chiefly with the question of the frequency of serious cardiac lesions as a sequel of chorea. After two years or more had elapsed from the time of the onset of the acute attack Osler looked up 140 cases, and found in 72 signs of organic disease. Osler mentions also Stephen Mackenzie, who in 33 cases, which were examined after the lapse of two years, found 60.6 per cent. affected with cardiac lesions, and Donkin, who in 44 cases found 18 similarly affected at the end of the same time.

"I have traced 53 cases of chorea that have been under my own care, but have excluded all those in which the time of onset of the chorea was not more than three years before the time of examination. Of these 53 cases, 32 presented no murmurs, with the exception in a few instances of a pulmonary murmur probably due to anemia. Murmurs obviously due to organic disease were heard in 18 instances, and with these must be classed 2 cases which had died obviously of cardiac disease, making 20 in all in which serious cardiac lesions were or had been present. In the fifty-third case a systolic murmur was audible at the apex and another at the base. The nature of the apical murmur was somewhat doubtful. It may or may not have been due to anemia from which the girl to some extent suffered. Of the murmurs obviously due to organic disease, 9 were presystolic, 8 mitral systolic, and in 1 to and fro aortic murmurs were present.

"In passing it may be mentioned that the fact that in only 9 cases a presystolic murmur was audible is a point of some interest. Inflammation of the mitral valve, if it result in permanent defect, almost invariably by degrees produces stenosis of the mitral orifice. Puckering of the mitral valve cusps, allowing regurgitation only, may almost be described as a myth. It is scarcely necessary to remark, however, that a stenosed mitral orifice, with very few exceptions, allows regurgitation, and the systolic murmur due to this regurgitation may not uncommonly be the only murmur heard. Possibly in some of the 8 cases in which only a systolic murmur was heard mitral stenosis may have been present, but that nothing more than dilatation of the left ventricle, in which the mitral orifice shares, need exist in such instances, was shown by one of the fatal cases.

"Osler mentions that in 17 of his cases functional disturbance was present, and in some of these, murmurs which were thought to be probably secondary to anemia were heard. No murmurs, however, may be present after chorea, and yet obvious weakening of the heart may be present. In at least 4 of my cases in which no murmurs were audible, this weakening of the heart, judging from what the boys or girls said of their capacity for exertion, appeared to be definite.

"A point to be considered in connection with the frequency of cardiac lesions following chorea is the occurrence of rheumatism. Of the 32 cases in which no murmurs were heard in only 6 cases a history of definite rheumatism or of pain in the joints could be obtained, whereas in the 20 with cardiac lesions rheumatism had been present in 8. Osler's statistics on this point are very similar. Another question to be considered is whether repeated attacks of chorea are more likely to result in damage to the heart than one attack. Curiously enough, of 14 of my cases that had only one attack, 7—that is just half—had cardiac lesions, whereas in some in which attacks had been frequent the heart remained healthy. Thus the heart remained healthy in one case where there had been six attacks of chorea, and in another where there had been seven. In 15 of Osler's cases in which there had been three or more attacks, the heart remained healthy. A fact which also seems to me to be noteworthy is that of the 20 cases with permanent cardiac lesions, in 13 I examined the heart when the patient was suffering from the first or only attack of chorea, and in only one of those no apical murmur was to be heard. Some of these last-mentioned details seem to suggest that if the heart escapes during the first attack of chorea it is not likely to suffer during any subsequent attack.

"It is necessary, however, to consider in this connection the importance of murmurs heard during the acute stage of chorea. Murmurs are frequently heard both at the apex and at the base. The basic murmur, which was present in 23 of my cases when they were first seen, is not uncommonly described as hemic, and an associated systolic apical murmur may be considered to be of the same nature. It is not necessary, however, to conclude that these murmurs, when heard in cases of chorea, have any connection with anemia. A loud pulmonary murmur can certainly occur when there is no anemia, and may be so loud that, when conducted to the right of the sternum, it may be mistaken for an aortic systolic murmur. Not long ago I was calling upon a medical friend, who took the opportunity of telling me that he had a case of dyspnea, of sudden onset, in which I might be interested. On examination of the chest a loud and widely-conducted basic systolic murmur was found to be present, which my medical friend thought was aortic. Considering, however, the murmur to be pulmonary, not aortic, and believing as I do in Dr. Foxwell's explanation of the pulmonary systolic murmur, I thought the main abnormal condition of the heart was dilatation of the right ventricle. A few days later a necropsy proved that my suggestion was correct, and that the aortic valve and aorta were quite healthy. In another similar case, where a strong healthy sea captain was seized with sudden dyspnea, and a loud basic murmur was audible, after death the aortic valve was found free from disease, and the cause of the cardiac failure proved to be a gumma of the septum ventriculorum. Pulmonary systolic murmurs present in cases of chorea are with little doubt an indication of some dilatation of the right side of the heart, and systolic apical murmurs generally an indication of dilatation of the left side. The dilatation may as reasonably be attributed to the action of micro-organisms or of toxins upon the heart muscle as to anemia. Opportunities of examining the cardiac muscle in fatal cases of chorea in which pericarditis is absent are not common. Recently, however, I have had such an opportunity. Microscopical sections of the cardiac muscle stained with Sudan iij and hematoxylin displayed very definitely the presence of fatty degeneration of widespread character. Commonly, fatty degeneration, especially that associated with anemia, affects some muscular fibers more than others; but in this case, although in none the degeneration was extreme, every fiber in all the sections examined was dotted throughout with small granules of fat, the distribution being for the most part uniform, except that in many fibers the fat granules were most numerous in the neighborhood of the ends of the muscle-nuclei.

"It should be added that whether a systolic apical murmur heard during the acute stage of chorea be allowed or not to be due to a toxic condition of the car-

diac muscle causing dilatation of the heart, it is interesting to note that in many instances the murmur disappears. This happened in 12 of my cases. In most of those, it is true, the systolic murmur was not very well marked, but in 3 it was described as high-pitched. Curiously enough, however, in another case, one of those included in the 20 with cardiac lesions, the girl was examined a few weeks after she had recovered from her first attack of chorea, when a high-pitched systolic murmur which had been present was found to have disappeared; yet when the girl was examined nearly seven years later a loud and widely-conducted systolic murmur was audible. There had, however, been another attack of chorea.

"Osler's large number of cases gives a higher percentage of serious cardiac lesions following chorea than my own; but Donkin's series gives results approximately similar. Osler's cases show a percentage of just over 50 per cent. of cardiac lesions, Donkin's, however, only a fraction over 40 per cent., and mine a fraction under 40 per cent. The smaller number of cases of Stephen Mackenzie, however, gives as high a percentage as 60.6. Roughly, perhaps, we may say that about half the patients who suffer from chorea will be found within a a year or two to be suffering from cardiac disease, which can be detected upon auscultation. It should be borne in mind also that in a few cases in which no murmur can be heard the heart has probably been weakened by disease of the myocardium.

"In considering the probability of heart disease following chorea, it is well to remember, however, that when there is no history of rheumatism the likelihood of damage to the heart is comparatively small. It appears, also, that if no signs of affection of the heart can be detected during the first attack of chorea the heart will probably not suffer during any subsequent attack.

"It must not be concluded, however, that apical murmurs heard during the first attack are necessarily permanent. Systolic murmurs will disappear, and it is scarcely necessary to add that the dull diastolic sound so commonly heard over the hearts of children temporarily enfeebled from various causes, must not be considered as the precursor of a presystolic murmur, though, of course, in later years in some instances a presystolic murmur will be found to be present."

**Citrate and Iodide of Potassium.**—Dr. William Ewart said: "I think that the hesitation I share with many in prescribing large doses of salicylates, in the absence of obvious rheumatic symptoms, might be best overcome if Dr. Lees could supply evidence that they availed to curtail the duration of the attack. The frequent occurrence of slowing of the heart's action is an argument for avoiding overdoses. May not some of the good results noted have been due to the anodyne effects of the large doses of sodium bicarbonate? The efficacy of carbonic acid in relieving spasm and nervous distress is well known, whether the gas be inhaled, injected into the rectum, or disengaged in the stomach from its watery solutions or its salts. I have long discarded the combinations with the salicylates of the alkaline bicarbonates in large and frequent doses in rheumatic fever, because of the danger of setting up permanent gastric dilatation from the constantly recurring distentions with carbonic acid gas. I prefer to use the citrate of potassium, and invariably administer the iodide also, as suggested by Dr. R. Caton."

Dr. G. J. C. Thomson asked why large doses of the salicylates should not be given as soon as the patient came under observation, just as in rheumatic fever, in order to get the patient quickly under the full influence of the drug.

**Pathology of Chorea.**—Dr. F. J. Poynton said: "It is chiefly upon the pathological aspect of this question that I wish to speak a few words. I think we must maintain a philosophical attitude of mind in the study of chorea and recognize that positive facts are of greater value than negative, for there are great difficulties in such a study, because of the rarity of fatal chorea and because it is a condition which is liable to be considered from one point of view. Either by the neurologist as a nervous disease or by the bacteriologist with the aim of obtaining cultures. It is difficult to get both points of view studied, and the cases in which this has been done are comparatively few.

"Such facts as we have at present I would briefly tabulate thus:

"(1) Micro-organisms of the streptococcal group have been isolated from rheumatic fever. (2) They have been isolated from the cerebrospinal fluid and brain itself in chorea. (3) They have been demonstrated in the pia mater and brain. (4) Involuntary movements of a peculiar type have been recorded by Paine and myself and F. Meyer as resulting from intravenous inoculation of rabbits with such micro-organisms. (5) Identical bacteria are found in other rheumatic lesions in man, and are capable of producing the lesions of rheumatism in animals. (6) Chronic leptomeningitis has been noted in chorea by Dana. (7) The lesions found after death in acute chorea are such as one could explain on the view of an infection. I mean the minute thromboses and hemorrhages, occasional embolism, degenerative changes in nerve cells, and perivascular exudation commented upon by Dr. Lees."

**Hyperpyrexia in Chorea.**—Dr. Edmund Cautley said: "I have never yet met with a case of hyperpyrexia in chorea. Certainly if it occurs at all it is very rare. This may be urged as an argument against the view that chorea is 'cerebral rheumatism,' even though modified by the words 'in the great majority of cases.' In the worst cases, those in which there was much insomnia and excessive movements, I have obtained very good results by the frequent administration, every two or three hours, of small doses of chloral hydrate."

**"Air-hunger" in Chorea.**—Dr. George Carpenter said: "I wish to ask Dr. Lees his explanation of 'air-hunger,' and whether he has made any observations upon the blood in cases developing this symptom. I have found that salicylate of soda in excessive doses induces destruction of the red blood corpuscles in some instances. I have seen one instance of fatal hyperpyrexia in a choreic child, aged three years. I desire to call attention to the danger of arsenical multiple neuritis in unwatched cases, and I have seen several cases of shingles in those treated by arsenic. Albuminuria may also be produced. I do not regard arsenic as of much value in the treatment of chorea, and trust more to antipyrin. The latter drug sometimes produced measly and urticarial eruptions. The urine must be watched, for antipyrin in some cases gives rise to considerable albuminuria."

**Chorea Ascribed to Fright.**—Dr. Michael O'Sullivan said: "During the period of my connection with a children's hospital in Dublin I have had under my care 54 patients suffering from this disease. Forty-one of those were girls, whose ages varied from five to twelve years (the latter being the limit of age for admission of girls to hospital), and of boys there were only 7, whose ages were from five to ten years (the high limit for boys). The onset of the disease was, in a number of cases, ascribed to fright, such as being attacked, but not injured, by a dog, or in different other ways. The spasmodic and involuntary movements supervened after two or three days in most cases. On examining into the previous history of these children I found in most of them a rheumatic history of some sort. In some there was an account of rheumatism in the parents,

which, so far, had not shown itself in some of the children. In others there was a distinct history of the patient having had a genuine attack of rheumatism, and others complained of growing pains, which I consider are closely associated with a rheumatic tendency. Again some of the patients had rheumatic attacks during the progress of chorea. Of the various cases I have had under my care 50 per cent. had well marked organic murmurs, very few of which disappeared with the disease. I have, however, seen two undoubted cases of mitral regurgitation which got quite cured as the choreic symptoms passed away. Patients who have been without murmurs on admission have, however, often developed them during the progress of the disease, and these generally pursued the same course as the others. The lesion I have found most common in those cases of heart disease is mitral regurgitation.

"The various symptoms of chorea are too widely and thoroughly known to require recounting. There is one item which I have never seen mentioned by any author, and I myself have commonly observed in cases of chorea, and that is the large size and more or less flabby condition of the patients' tongues. I may say I rarely see patients without that condition of tongue. I had once a peculiar case of chorea (temporary) under my care. This was an attack which followed a rather prolonged administration of nitrous oxide gas, and lasted only about an hour. This patient was a girl seventeen years of age.

"The treatment which I adopt in almost every case is a combination of rest to mind and body. To prevent children learning lessons, and removing them from surroundings which might be too exciting, and capable of giving rise to frights and emotions. Warm baths are very useful, and easily digested nutritious food is absolutely necessary. Patients who are very violent should have their beds padded, and should be carefully watched that bedsores may not occur.

"With regard to medicinal treatment, I may say arsenic is practically the only drug I use. I prescribe it in 10 to 15 minim doses from the beginning, well diluted with water, and given during meal times. This occasionally disagrees with the stomach, and should then be discontinued for a time, when it will generally be found that the gastric disturbance will not recur on the readministration of the drug. In severe cases I prescribe chloral, and have on occasions given chloroform by inhalation. When chorea is complicated by rheumatism I always advise salicylate of soda."

Dr. J. R. Logan said: "Although shingles occurs in choreic patients taking arsenic, it is not always due to the drug, and may depend upon some trophic influence of the affected nervous system. I have seen well-marked herpes zoster in a child, with chorea, who was not taking arsenic."

Dr. Lees, in closing, drew attention to the necessity for sufficiently large doses of salicylate in the treatment of rheumatism and chorea. If the dose were too small, the desired results would not be obtained, and if the dose were too rapidly reduced there was the greatest probability of relapse. He related cases in illustration of this. He had seen one fatal case of hyperpyrexia in a choreic child.

**The Relation of the Thyroid Gland to Marasmus.**—Prof. John Ruhrah, of Baltimore, said: "The pathology of infant life has been to a certain extent a very much neglected field, and I feel positive that a rich harvest awaits the workers who will be painstaking enough to study both in the ward and in the deadhouse. In most places the necropsies on infants are hastily done, and the record frequently made in the report, 'Nothing abnormal noted.' As a matter of actual fact regarding many organs during infancy there are few who know normal from abnormal or who can tell from a microscopical examination what the microscope will reveal. There are, I am sure, clinical entities with well-marked lesions which are waiting to be described.

"As you all know, one frequently sees an infant sicken and die without diagnosis during life, and no adequate explanation after the necropsy has been made. Many of these cases come under the head of marasmus, and it was with the intention of trying to throw some light on this interesting condition that especial care was taken with our necropsies on infants. The following brief report, which I hope will stimulate others to undertake similar studies, is based on about 85 necropsies. The first 23 have been carefully tabulated by my colleagues, Dr. Stokes and Dr. Rohrer and myself, and while the remainder have not been tabulated they have been studied, and the conclusions reached from the first twenty-three remain unchanged.

"It is a curious fact that the most characteristic lesions of marasmus, excepting the wasting of fat and muscles, while known for many years, is not mentioned in any of the text-books on the diseases of children. This lesion is a wasting of the thymus gland which will be described later.

"Parrot, in 1877, called attention to the disease which he called athrepsia, the so-called wasting disease of infants, known also as marasmus, simple atrophy and atrophia primitiva infantum. The term inanition, also used, should be restricted to those acute cases of starvation which have a typical course and characteristic symptoms.

"There are two conditions in which we see atrophy in infants. The primary cases, where the cause is as yet unknown and those following definite pathological conditions, or the secondary cases. The dividing line cannot at this time be definitely drawn. All cases occurring in the course of the easily recognized diseases may at once be placed in the group of secondary cases, those following tuberculosis or syphilis for example. Clinically most cases are seen in infants which have had improper food and care. Some authors would also place these in the list of secondary cases. They would place under the head of primary atrophies only those where the assimilation was at fault; or, in other words, those cases receiving proper care and a physiologically correct diet. This is, we think, a division practically useless; and for the present until we have definite information the cases should be divided, on a pathological basis, into those where there are lesions of definite diseases, and those where there are no special and constant lesions except the wasting of the muscles and the body fat, and as we shall see of the thymus gland as well.

"We may safely assert, I think, that the trouble is not due to the amount of food ingested nor to the amount absorbed from the intestinal tract, but that it is due to malassimilation of the food material in the body. Whether the thymus gland has anything to do with assimilation or not we are not prepared to say, but it is certain that the thymus gland bears a direct relation to the state of the nutrition of the body. It increases in size until about the second year, when it remains stationary, growing relatively smaller when compared to the size of the growing body. At puberty, when the body growth is largely over, it begins to atrophy and at about twenty-five years of age, when the body has attained its full growth, it is gradually replaced by fatty and connective tissue.

"Herard, at a subsequent date Friedleben, and more recently Mettenheimer, have pointed out the relation of the size of the thymus to the state of nutrition of the body. Of this there can be no doubt, as it rests on a firm basis of trustworthy observation. The function of the thymus is as yet unknown, and the limited time at

my disposal prevents my even mentioning the observations and theories concerning it. The thymus gland weighs about 12 grams at birth. Histologically, it consists of a connective-tissue framework, holding up a parenchyma consisting of a cortex and medulla, which are similar in structure, but the cortex contains normally many more cells than the medulla. The parenchyma consists of a network of endothelial cells resembling the reticular spaces of the lymphatic structures. This space is filled with lymphoid cells, and also with a few neutrophilic and eosinophilic leucocytes, and with a few giant cells. Here and there in the structure are little islands of epithelial cells with a peculiar concentric arrangement not unlike that found in the concentric bodies of an epithelioma. These are the so-called Hassal bodies or corpuscles. They are the remains of the epithelium, which forms the principal part of the thymus gland during embryological development.

"Our studies cover 18 cases of marasmus. The average weight of the gland was 2.2 grams. Excepting the terminal infection, the atrophy of the thymus was the only lesion found in any of the autopsies. The changes in the gland consisted in a great atrophy. Histologically, the fibrous capsule of the gland is thicker than normal, and the trabeculæ are also greatly thickened, and the increased interlobular tissue frequently cuts the lobules up into irregular masses. Sometimes there is more fibrous tissue present than there is lymphoid structure. In well-marked cases there is more reticular tissue present than lymphocytes and leucocytes. In most of the cases there was an increase in size and a hyaline degeneration of the Hassal bodies.

"The state of the nutrition of infants may be estimated by a microscopical examination of the thymus. In those of normal infants the structure of the thymus is unaltered, and the differentiation between cortex and medulla is plainly visible. In moderate atrophy the cortex and medulla are not easily distinguished, while in severe atrophies the changes mentioned above are plainly seen.

"In secondary atrophy the change is one of degree, and we found in our cases the average weight of the thymus to be 3.41 gram.

"We tried the administration of the thymus gland tablet in cases of marasmus, and as far as could be determined there were no changes produced by the use of the gland in the dried form. We arrived at the following conclusions: (1) Atrophy of the thymus gland is always found in cases of infantile atrophy. (2) The condition of the thymus is an index of the general nutrition of the infant. (3) The state of the nutrition in infants may be estimated by a microscopic examination of the thymus at autopsy."

Dr. F. J. Poynton, in the discussion, asked Prof. Ruhrah's opinion upon a remarkable condition in children. Roughly, the symptoms were (1) enlargement of the thymus, even giving rise to a dulness behind the manubrium, (2) paroxysmal cough, (3) sudden death. These cases had been long recognized, but whether or not the symptoms were dependent upon the condition of the thymus was uncertain. He did not remember any relation between the size of the thymus and the condition of the body in these cases. They were very dangerous cases, and he raised the question because he would like to hear the experience of Prof. Ruhrah in this matter.

Dr. H. Ashby asked the writer of the paper for any observations he had made on "thymus death." In some of these cases the infants were well nourished and perfectly healthy, without any signs of rickets. Death occurred suddenly, and at the necropsy an enlarged thymus was found.

Dr. W. Ewart, in connection with the mode of causation of so-called "thymus death," called attention to the probability that the enlargement of the gland was not the only cause. Some other factor, such as pulmonary congestion or gastro-intestinal distention, of a more sudden nature, must be admitted. But the chief factor was, in his estimation, the individual cardiac weakness, which, in the adult, showed itself in the tendency to fainting and to sudden death.

Dr. George Carpenter was no believer in the condition of thymic asthma or of sudden death from an enlarged thymus. He had seen cases of enlarged thymus which did not produce any symptoms. He had also seen cases of tuberculous disease of the thymus which produced mediastinal tumors diagnosed during life, and which did not induce thymic asthma or sudden death. An enlarged thymus was a well-known physiological condition of infancy, and it did not produce clinical symptoms. He had no doubt in his mind that thymic asthma and sudden death in some cases were due to post-nasal catarrh, sometimes in association with adenoids, a condition which was not recognized and which he drew attention to. He called attention to a fact that should be widely known that digital examination of the nasopharynx produced in some instances a cough indistinguishable from whooping cough, and that it also produced spasm of the larnyx. His firm conviction was that so-called thymic asthma and sudden death from the thymus were in many instances in reality due to spasm of the larynx, which in the fatal cases did not relax. Thymus death was often death from laryngismus stridulus, and the sooner this was recognized the better. Pay more attention to the nasopharynx and thymic asthma will be a less fashionable explanation.

Dr. R. B. McVittie asked if the atrophic conditions of the thymus were, in Professor Ruhrah's experience, in any way associated with syphilis. In the cases which he had seen of sudden death, which would be likely to be attributed to what was called thymic asthma, the children were always very stout. It seemed to him most probable that they were cases where the heart was likely to be constitutionally feeble and easily stopped by some comparatively trivial circumstance, such as laying the child down after a full meal.

Dr. Theodore Fisher said the position he had always taken up was that in cases of sudden death the children were better nourished than those dying of chronic disease, and a normal thymus was consequently thought to be enlarged. He thought, in most of the cases, death was due to laryngismus stridulus, though evidently the case mentioned by Dr. Ewart would not come under that heading.

Dr. Ruhrah, in closing, said that as regards thymic asthma and thymus death he had had no personal experience. There were undoubted cases of thymus death, but he was inclined to think that some of those reported were due to other conditions, and that the normal thymus seemed unusually large, as the atrophied thymus was the one with which most of them were familiar. In one case which he observed the child died rather suddenly with convulsions and edema of the lungs. Quite a large thymus was found, but about a quart of potato salad was found in the intestinal canal. His investigations were undertaken with the idea of throwing some light on the pathology of marasmus, with hopes of finally finding some therapeutic measures of value.

**The Age for Operating in Cleft Palate.**—Dr. R. W. Murray said: "There is a considerable difference of opinion among surgeons as to the most suitable age for operating for cleft palate. Some delay operating until the child is between three to six years of age; others, again, operate during the first few weeks of life.

"In the case of a child born with a cleft palate there can be no doubt, from a purely theoretical point of

view, that the sooner the cleft is closed the better; at the same time, 'it is often wise to effect a compromise between that which is theoretically most desirable and that which is practically most advantageous, things being as they are.' The main object with which an operation for the closure of a cleft of the palate is undertaken is that the powers of speech may thus be rendered more perfect than they otherwise would be. If the operation is postponed until the fourth or sixth year of life, the child has then learned to talk, and necessarily to talk badly, a habit once acquired very difficult to overcome completely. At the same time, it must be remembered that the defective power of articulation in these cases depends upon other factors than the mere gap in the palate. I would particularly draw your attention to the fact that, if the cleft involves the bones of the hard palate, articulation will never be perfect, even though the child has been operated upon early in life, and the operation successfully performed. For example, if a child has a simple hare-lip, the alveolar margin and the palate being perfectly formed, the subsequent powers of speech will be in no way affected. But if as well as a hare-lip there is a slight notching in the alveolar margin (not, of course, amounting to a cleft palate), then, however early and however perfectly the deformity of the lip may be operated upon, the child will always talk with a lisp. The same holds good in regard to the posterior structures of the palate. If the cleft involves the whole of the soft palate, but does not include the hard palate, then, provided the cleft is closed before the child has learned to talk, there will be no noticeable defect of speech in after years. But if, on the other hand, the bones of the hard palate are involved, then, in spite of an early and successful operation, there will be a permanent defect in articulation, though this defect will not necessarily be directly proportionate to the amount of the bony deformity.

"The explanation, I believe, is that when the cleft involves the hard palate or alveolar margin, this defect in development is not limited to the structures of the mouth but also includes the nasal chambers, which are so largely concerned in the production of the voice, and therefore the imperfect articulation so characteristic of persons born with a cleft of the hard palate persists even though an operation for the closure of the cleft has been successfully performed. As further confirmation of this view that the cleft in the palate is not entirely responsible for the nasal character of the articulation, one has only to remember that from time to time we see children who speak as if there was a cleft of the palate, but on examining the mouth the only defect noticeable is that the palate is very highly arched, thus encroaching upon the nasal chambers. I believe this to be the explanation of the defective articulation in these cases, a condition which one could not hope to remedy by any operation upon the highly-arched palate. If then it is true that provided a cleft of the soft palate is closed before the child has learned to talk, the result, so far as speech is concerned, will be perfect, it necessarily follows that the operation for the closure of such a cleft should take place somewhere between the time of birth and say the end of the second year, always provided, of course, that the health of the child will permit of it. For my own part, I have no hesitation in saying that within this age limit the later the operation is performed the better.

"I know there are surgeons who hold different views, and who advocate and practise closure of the cleft during the first few weeks of life; in fact, in a case of hare-lip and cleft palate they operate upon the palate before operating upon the lip. In my experience this is a mistake, for every one will surely admit, other things being equal, the older the child the easier the operation, and, so far as a cleft of the soft palate only is concerned, I am convinced that a perfect result as regards articulation may be obtained provided the operation is performed about the end of the second year, and nothing better than this can be hoped for by operating during the first few weeks of life. On the contrary, during the first few months of life the tissues are so friable and the amount of material out of which to make a soft palate with so scanty, that after paring the edges there is very little soft palate or uvula left. This is a matter of considerable importance, for I believe the ultimate result in respect to articulation largely depends upon a good and freely movable soft palate.

"When, as is usually the case, there is a complete cleft both of the lip and of the palate, I operate upon the lip when the child is about three or four weeks old, and delay operating upon the hard and soft palate until about the end of the second year. It is quite remarkable how the closure of the lip influences the subsequent growth of the hard palate. I have noticed in a large number of cases where at the time of the hare-lip operation the gap in the alveolar margin of the palate has been considerable, that several months after the closure of the lip the alveolar gap has practically disappeared. This is to my mind a strong argument in favor of delaying the operation upon the palate, for the narrower the cleft, the easier the operation and the greater the probability of success. In this class of case, however, where the hard palate is involved, the subsequent powers of articulation, for reasons I have already mentioned, will always be somewhat defective. If, on the other hand, the soft palate only is involved, the prognosis is much more hopeful. I know of several children upon whom I operated for cleft of the soft palate before they could talk, and these children now articulate quite naturally, it being impossible to detect from their speech that they ever had cleft palates.

"I would emphasize the importance of training these children after operation to articulate correctly; they have the greatest difficulty with the 's' and the 'th,' and the plan I usually adopt is to get the mother to teach the child some nursery rhyme as 'Seesaw, Margery Daw,' and ask the child to repeat it to me from time to time."

Mr. Arbuthnot Lane, in discussing Dr. Murray's paper, said that he operated as early in life as possible—indeed, he preferred the day after birth. He gave the following reasons for this procedure: (1) That the nasopharynx was sooner exposed to the influence of the mechanical factor upon which its development depended; (2) that the operation was much easier at this age and more certainly successful, because of the absence of teeth and the much greater flap obtainable; (3) the child being in good condition it repaired well, and it displayed no irritation or annoyance whatever because of the operation.

Dr. H. Ashby asked the President for his experience in tracing in after-years the progress in articulation of those infants operated on during the first few weeks of life. There could be no doubt that those operated on when five or six years old talked with a nasal twang for many years, and required long training.

Dr. F. J. Poynton wished to know if the risk to life was not a real factor in operating upon a child under a week old. This was a most vital point. A dead child with a palate closed was a tragedy. The operation was a decorative, not a vital one. He would like to know from Mr. Murray and Mr. Lane if the dangers to life were not a reality in the first week of life.

**Discussion on Congenital Dislocation of the Hip.**—Dr. F. F. Burghard said: "Although the subject of congenital dislocation of the hip has been one of much interest to the profession ever since the publication of

the work of Hoffa and Lorenz, there has been an increased activity in the matter within the last two years, which is largely due, no doubt, to the use of the X-rays, whereby results can be accurately checked and vague general statements replaced by precise observations. Extended experience leads me to confirm the view that I enunciated in a paper read before the British Medical Association in 1901, that certain cases are more suited for one method and certain for the other, and that careful discrimination is needful to ensure success in treatment."

**Anatomical Changes Met with in Congenital Dislocation.**—"In order to arrive at a just conclusion as to the best method of treatment it will be well to mention briefly the various anatomical changes met with.

"The most pronounced and invariable change, and one that is present from the earliest period of life, is found in the acetabulum; it is also of primary importance in the treatment of the affection. Instead of being the normal hemispherical cup looking downward, outward, and forward, it is a shallow triangular depression looking almost directly outward, and with its apex directed upward. Moreover, its upper margin, which in the normal joint plays a prominent part in retaining the head of the bone in the acetabulum, is very defective, and is quite incapable of exerting any retentive function. It is this shallowness of the acetabulum that renders easy the reluxation that so often occurs after an apparently successful reduction of the dislocation.

"Another point of the highest practical importance, and one that does not seem to have hitherto attracted its due amount of attention, is the arrangement of the capsule of the joint and the changes that different portions of it undergo. It serves to explain a number of cases in which the 'bloodless method,' although apparently successful at the time, fails eventually, and dislocation recurs a few days or a few weeks after the operation. An examination of museum specimens and an extended experience of the open operation has impressed upon me the great importance of this anatomical factor. Attention was first called to the matter by Hoffa, and its importance has been more recently emphasized by Bradford and Nicholls. The following account, translated from Hoffa's well-known work on Orthopedic Surgery, puts the matter concisely.

"'The capsule rapidly undergoes alterations in shape and assumes a somewhat hour-glass form. Starting from the posterior edge of the acetabulum it passes over the head of the bone, over which it is accurately applied, so that the outline of the head can be seen clearly beneath it. It then runs forward and downward and becomes firmly adherent to the acetabulum, so as to make with this flattened cavity a narrow pouch, the so-called "acetabular pocket" of Lorenz, from which the ligamentum teres, when present, emerges to reach its insertion into the head. This lower portion of the capsule thus forms a sort of diverticulum which only communicates with the upper spacious capsular cavity, in which lies the head of the bone, by an isthmus, the so-called *rétrecissement* of Bouvier. This narrowing is really caused by the passage of the iliopsoas tendon across the capsule at this spot. It is not in this form only that the capsule undergoes changes; its consistence also alters. The entire anterior and inferior portion becomes abnormally thickened, so that the portion lying like a lid over the acetabulum becomes exceedingly dense and unyielding. In this the various capsular bands, and especially the Y-ligament, play an important part.'

"These changes in the structure and arrangement of the capsule have a twofold action in preventing a true cure of the dislocation. In the first place it may be impossible to cause the head of the bone to pass beneath the lid formed by the anterior part of the capsule and lie truly in the acetabulum without some open operation accompanied by detachment of the capsule from the acetabulum. In the second place this capsular lid may become interposed between the head of the bone and the acetabulum in cases in which the bloodless reduction is apparently successful, and this will lead to such an unstable joint that reluxation will readily recur. That this is the true explanation of some of the failures of the 'bloodless method' I have been able to assure myself when practising the open operation; it has apparently been possible to reduce the dislocation by manipulations, but examination by the finger in the wound has shown that the head of the bone has merely been made to lie over the acetabulum, the thickened anterior wall of the capsule forming a dense partition between them. In other words the case is one of spurious reduction.

"Nor are the changes that occur in the femur of inferior importance. Foremost among these is the increase that occurs in the angle made by the long axis of the neck of the femur with the transverse axis of the femoral condyles. In the normal subject this angle varies between 15 and 25 degrees, but in every case of congenital dislocation it is increased, and may be as great as 80 or even 100 degrees. This torsion of the femoral neck generally takes place in the forward direction, so that, when the head is properly in the acetabulum, the entire lower limb is rotated more or less strongly inward, according to the extent of this so-called 'angle of femoral torsion.' It is said that this torsion may be so extreme in adults as to require an osteotomy to remedy it. Personally, I have only found it very marked in three cases; in two it yielded to well-applied traction and movements, but in the third case—which is still under treatment—the torsion is very extreme, being, as nearly as I can judge, quite 90 degrees. These three cases are all young children.

"Another very important change in the femur is the alteration in the angle made by the neck with the shaft. The normal angle is about 120 degrees, varying between 110 and 140. In cases of congenital dislocation, however, it undergoes diminution, and may be as small as 90 degrees. The diminution is slight before the child begins to walk, and its degree is to some extent proportionate to the length of time that has elapsed after the child has learnt to walk.

"The changes in the head of the bone itself are rarely marked, except when the dislocation has persisted untreated for years. In early life the head is rather diminished in size, and its general outline is somewhat pyramidal from flattening of its inner aspect against the outer surface of the ilium, but it is only when the dislocation has lasted for several years that the irregular mushroom-shaped head described in the text-books is seen.

"The alterations in the ligamentum teres are various. As a rule it is absent altogether; when present it is always elongated and often very thin. The changes that take place as growth progresses are not constant either in kind or in degree. The most important alteration—and one that is very common as far as my expereince goes—is a change in the anatomical variety of the dislocation; that is to say, a dislocation which in early life is a true dislocation upward becomes, as life advances, a dislocation upon the dorsum ilii. When this occurs there is the characteristic loose joint, the extreme waddle in walking, and increased shortening. The acetabulum always gets shallower as the child gets older, and at the age of sixteen I have found it barely perceptible to the finger when the joint was cut down upon. It invariably remains, however, as a shallow but quite definite depression throughout life. The diminution in the angle made by the neck of the bone with the shaft increases, and the head assumes the typical

mushroom form. The anterior portions of the capsule become still more shortened and thickened. It will thus be seen that there is a definite reason for the admittedly great want of success in the treatment of cases that have been allowed to reach some age before the affection is taken in hand. At the age of puberty the anatomical changes are so advanced that it may be mechanically impossible to get the head of the bone into the normal position in the acetabulum. The usual result of untreated cases is a large, loose, sliding joint between the head of the femur and the outer surface of the ilium, with its concomitant deformity, although the case reported by H. Morestin shows that a perfectly stable, though imperfect, joint may occasionally arise even without treatment of any kind.

"The form of dislocation met with in practice varies somewhat according to the age at which the patient comes under notice. It seems to be the general impression that there is a true dorsal dislocation in the majority of cases, the head of the femur moving freely over the outer surface of the ilium. This is no doubt the case in the older children—those, for instance, over six years of age; but in my experience the common form of dislocation seen in young children, and probably the almost universal form at a very early age is a true dislocation upward beneath the anterior superior iliac spine, the so-called 'supracotyloid' form. This form of dislocation is, however, an unstable one, and, as age advances and the weight of the body increases, it is apt to become transformed into the common dorsal dislocation, the head passing on the dorsum of the ilium. There is yet a third form that is occasionally met with; here the head of the bone passes upward and backward, and occupies a position above and behind the normal acetabulum intermediate between the two varieties just described. This variety is very unstable indeed, and soon becomes transformed into the true dorsal form. There is much less interference with the normal gait when the dislocation is directly upward, and it is these cases that are often overlooked.

(To be Continued.)

## BOOK REVIEWS.

Reference Handbook of the Medical Sciences. Embracing the Entire Range of Scientific and Practical Medicine and Allied Science. By various writers. A New Edition completely Revised and Rewritten. Edited by Albert H. Buck, M.D., of New York. Vol. VI, Mos-Rye. William Wood & Co., New York.

The present volume contains an immense amount of material, well systematized and thoroughly up to date. We cannot add much to our previous encomiums of this work, save to repeat that we know of no single work of reference which in any way compares with this "Reference Handbook." It is a veritable *vade mecum* and, the reviewer believes, should be found in the library of every wide-awake practitioner of the country.

Articles of special interest are numerous. We might signalize some for special mention. Thus the article on Muscles with Muscular Dystrophy; a consideration of the subject of Nasal Cavities with their attendant diseases; the article on Naval Hygiene, which is remarkably full, as is also the article on Nematodes might be chosen. The general consideration of Nerves, Nervous Injury, Neurology, Neurasthenia, Neuritis, Neurones and Neuroses is thoroughly modern and complete.

A very interesting article is one on the relation of Occupation to Disease, and we do not know where we have seen an article on Diseases of the Esophagus so well considered from all points of view as that in the "Reference Handbook." The discussion of the Ophthalmoscope is too full even for a specialist. Organotherapy, Pain, Pancreas, Paralysis and its related phenomena are all well considered. There is a very excellent plate on the Eggs of Human Parasites, a better collection than we have seen anywhere. Other sections worthy of mention are Perineum, Phagocytosis, Pharmacopœias, Placenta, Plasmon, Poisonous Plants, Poisonous Reptiles, Poisons, Premature Infants, Quarantine, Recruits, Reflexes, Refuse Disposal, Reparative Surgery, Resection of Joints, Rheumatism, and Roentgen Rays.

As this excellent book nears completion, its masterly character becomes more and more evident and we hope for it the wide popularity that the work of both editor and publisher deserves.

The Praxis of Urinary Analysis. A Guide to the Chemical Analysis of Urine, with Directions for Preparing Artificial Pathological Urines for Practising the Various Tests and an Appendix on the Analysis of Stomach Contents. By Dr. Lassar-Cohn, Professor in the University of Königsberg. Authorized Translation from the Author's Enlarged and Revised Second Edition by H. W. F. Lorenz, A.M., Ph.D. (Berlin). John Wiley & Sons, New York.

This booklet of 56 pages contains only what is absolutely essential for the chemical analysis of the urine; it being the intention of the author to make the subject appear in its simplest form and to avoid confusing the beginner with many tests. An equally brief chapter on stomach analysis is appended. The volume seems to be intended more for pharmacists, as the microscopical examination of urine is not touched upon and the physician would really have to resort to another treatise for a complete analysis. An original feature is the preparation of artificial pathological urines for practising the various tests.

Post-Mortem Pathology. A Manual of Post-Mortem Examinations and the Interpretations to be drawn therefrom. A Practical Treatise for Students and Practitioners by Henry W. Cattell, A.M., M.D., Pathologist to the Philadelphia Hospital and the West Philadelphia Hospital for Women, etc. J. B. Lippincott Company, Philadelphia and London.

We have long felt the want of a good English book on gross pathology, and those of us who are obliged to do pathological work have always been conscious of how poor our own literature is in books on this subject. The volume before us cannot be recommended too highly; it stands on the same level with Orth's and Nauwerk's works, and should not be missing in any hospital library. After chapters on General Consideration, Records and Note-taking, Post-Mortem Instruments and Their Use, and Care of the Hands, Virchow's and Orth's Methods of Performing a Complete Autopsy described in full with such modifications as law and custom in this country demand. Then the various organs are taken up in detail and their different pathological conditions described most graphically. New and original suggestions and practical hints abound everywhere. The restoration and preservation of the body is not neglected and in the chapter on the preservation of tissues for microscopic and macroscopic purposes, the methods of Kaiserling and Pick, so commonly employed in Germany at present, receive a detailed description. Comparative post-mortems, medicolegal suggestions and Prussian medicolegal post-mortems are each discussed in a separate chapter, and appended to the book there is a list of usual causes of death with synonyms. Last but not least, mention must be made of the numerous excellent illustrations in this volume; they are remarkably clear and illustrate the various steps so much better than words.

VOL. 83. NEW YORK, SATURDAY, SEPTEMBER 19, 1903. NO. 12.

## ORIGINAL ARTICLES.

### THE ETIOLOGY AND CHEMICAL PATHOLOGY OF GALL-STONES.*

BY C. A. HERTER, M.D.,
OF NEW YORK.

ALTHOUGH the methods of modern surgery have perhaps robbed gall-stones of some part of their medical interest by lessening their menace to life and by doing much to prevent their recurrence, gall-stone pathology remains a fascinating field for the experimentalist and is not wholly without promise for the student of preventive medicine and therapeutics. It is the purpose of this paper to deal with our present knowledge of the conditions that attend the production of human gall-stones, and, pointing out some gaps in this knowledge, to suggest problems for further research.

The well-known variety in gall-stones, as regards their chemical constitution and the arrangement of material within the concretions is in itself an indication that the conditions of stone-formation are not always the same. Thus the cholesterin stone, consisting almost wholly of cholesterin, disposed in radial crystals about a small débris center, speaks for a very different developmental history from that of the bilirubin-calcium stone containing little or no cholesterin. In the following pages some explanation will be offered for these varieties in chemical constitution.

*Origin of the Chief Constituents of Gall-stones.*—Since cholesterin and bilirubincalcium are by far the most abundant and regular constituents of gall-stones, it is desirable to consider their origin and the conditions attending their appearance as constituents of calculi.

1. *Cholesterin.*†—This monatomic occurs in bile from human fistulæ in only low percentage.‡ In bladder bile the percentage is somewhat higher.§ The greater proportion observed in the cystic bile can almost certainly be attributed in part to cholesterin derived from epithelial cells lining the gall-bladder and not to a concentration of the bile from absorption of water.

Of the origin of the cholesterin of the hepatic bile little is known. A part is probably obtained from the blood and it is likely that diseases attended by a considerable increase in the cholesterin of the blood (as in some cases of diabetes) lead to the passage of an excessive quantity of the compound into the bile, but it must be admitted that there is no convincing evidence on this point. There also remains much to be learned as to the origin of the cholesterin found in normal blood. We know that this substance can be obtained from columnar or cuboidal epithelial cells and that it occurs in the central nervous system. Probably it is a normal cleavage product of larger molecules, but its biological significance is still obscure.

When cholesterin is found either in the crystalline or amorphous state in larger or smaller concretions on the floor of the human gall-bladder it is commonly assumed that this cholesterin has been precipitated from a bile that is over saturated. In many instances this is doubtless a correct view, but I think it can be shown that many small masses of cholesterin arise in a wholly different way through the aggregation of very small globules of intra-epithelial material. From the gall-bladders of patients dying of chronic nephritis and other chronic diseases, are sometimes freed numerous small, dark, friable masses of less than pinhead size, which lie in the dependent parts of the bladder. On examining these masses with the microscope they are seen to consist of epithelial elements which have become highly granular and have lost their normal structure through degenerative alterations. This epithelial débris is commonly stained with bile pigment. It does not contain cholesterin crystals. Nevertheless when a drop of concentrated sulphuric acid is added to some of this material it gives a characteristic and marked reaction for cholesterin. The amorphous finely divided cholesterin which gives this reaction cannot reasonably be regarded as a precipitate from the bile but it is much more likely to be the direct derivative of epithelial cholesterin. The fact that the bile often contains an excess of cholesterin under these conditions is not opposed to this view, for one would expect that the bile would take up the cholesterin of epithelial origin until it has become quite saturated, after which there would be a liability to crystalline separation at any time.

It is probably true that cholesterin is sometimes separated from a saturated biliary solution owing to some alteration in the composition of the cystic bile which renders the lipoid material less soluble, but it is unlikely that such alterations in the solvent powers of the bile play an important part in the genesis of calculi. The solvent

*Read before the Congress of Physicians and Surgeons, May 13, 1903.

†Outline of Ritter's Method for Estimation of Cholesterin in Bile: Weighed amount bile is evaporated to dryness on H bath—and sodium alcoholate added. The whole is kept at a gentle boil on $H_2O$ bath for two to three hours—then alcohol evaporated off. The residue is taken up in $H_2O$—c.p. NaCl added, then evaporated. The thoroughly dried residue is placed in filter cap and extracted with pure dry ether in Soxhlet's extractor for nine hours. The ethereal extract is filtered, ether removed, and the residue, composed of cholesterin, is weighed. To purify, dissolve residue in a little hot alcohol, and add $H_2O$ to the solution in small quantities at a time. Cholesterin separates out, and may be filtered, dried and weighed.

‡Copeman and Winston found .099 per cent., Mayo Robson .045 per cent., Noël Paton and Balfour .062 per cent.

§Observations made by Dr. Baldwin in my laboratory indicate that the cholesterin content of human cystic bile is commonly about .1 per cent.

action of the bile for cholesterin depends in some degree on the biliary soaps and fats and especially on the bile-salts. A certain degree of alkalescence to litmus such as prevails in normal bile (human and canine) is favorable to this solution. There is no definite knowledge of any metabolic peculiarity or anomaly in man which leads to a diminished secretion of biliary salts.* Nor do we know of significant changes in the concentration of the soaps and fats. The reaction of the cystic bile in this connection deserves more attention than it has received but the opportunities of studying it in fresh human bile are necessarily very limited.

It is claimed by some writers that acid-producing bacteria give rise to an acid reaction of the bile.† There is, however, no satisfactory evidence that this occurs. The bile contains no appreciable reducing substances‡ and probably no fermentable carbohydrates. We know also that one organism, the typhoid bacillus, may be the sole excitant of gall-stones containing cholesterin although it is not an acid producer in ordinary media. Whether the cystic bile ever has an acid reaction in consequence of a diathetic acid intoxication cannot be positively stated but there are facts that render this most unlikely. Hence it may be said that although an acid bile is favorable to the separation of cholesterin there is no evidence at present to justify us in believing that pronounced acidification of the bile is essential to the formation of cholesterin gall-stones.

*Excessive Cholesterin Production is the Chief Factor in the Production of Cholesterin Concretions.*—The view that the cholesterin of gall-stones arises from the mucous membrane of the gall-bladder is not new. Budd suggested it in 1845, Bristowe revived it in 1887 and Naunyn became its earnest advocate in 1892. The facts that have appeared to speak most strongly for the local origin of cholesterin are two. First is the observation that epithelial cells desquamated from the mucous membrane of the gall-bladder soon undergo degenerative alterations attended with the production of new cholesterin, which in time may take on a crystalline form. This accords with the similar observation that degenerating epithelial cells derived from the bronchial mucous membrane in catarrh and putrid bronchitis often contain cholesterin. The occurrence of this substance in old pus and in old cysts also points to a local origin. Secondly, there is the observation, reported by Naunyn, that the administration of cholesterin to a dog was not followed by an increase of this lipoid in the bile. Although it is stated that the cholesterin was absorbed, the experimental conditions appear not to have been wholly satisfactory for testing the question whether an excess of cholesterin in the blood leads to an increased percentage in the bile* We cannot exclude the possibility that there are occasional disorders of nutrition attended with an increase of cholesterin in the blood serum and hence with an increase in the bile.†

Experiments made in my laboratory by Dr. Wakeman give strong support to the view that inflammatory conditions in the walls of the gall-bladder may lead to an increase in the cholesterin of the bile. Dr. Wakeman injected (under aseptic precautions) strong solutions of bichloride of mercury, carbolic acid, ricin, abrin and diphtheria toxin into the gall-bladders of dogs that had fasted for three days. After periods of three to four days the animals were killed. The gall-bladder walls were usually much thickened (especially in the bichloride series) and showed considerable proliferation and desquamation of epithelium together with congestion of the vessels of the submucosa. The solids of the bile were diminished in percentage in the bichloride series. The cholesterin of the bile was markedly increased in the bichloride series, in the carbolic acid series and in the ricin series, the change being especially noticeable in the cholesterin content of the solids. The abrin series and the diphtheria toxine series must be regarded as negative, which corresponds to the absence of structural changes in the mucous membrane of the gall-bladder. Some idea of these results may be obtained from the following table:

Table I.

Injection into dog's bladder of

| | | Normal | $HgCl_2$ | $C_6H_5OH$ | Ricin | Abrin | Diph. Toxin |
|---|---|---|---|---|---|---|---|
| Number of observations | | 20 | 12 | 7 | 6 | 5 | 8 |
| Amount injected | | | .02 to .1 grm. | .15 to .4 grm. | 9 to 12 mg. | 1 to 1.75 | .08 to .4 c.c. |
| Total bile, per cent. | | | | | | | |
| Cholesterin, | Average | .127 | .298 | .334 | .427 | .132 | .167 |
| " | Highest | .260 | .458 | .940 | .823 | .231 | .235 |
| " | Lowest | .051 | .137 | .056 | .076 | .070 | .054 |
| CaO | Average | .077 | .064 | .072 | .079 | .110 | .094 |
| " | Highest | .115 | .166 | .111 | .150 | .134 | .155 |
| " | Lowest | .047 | .018 | .045 | .033 | .077 | .055 |
| Total bile solids, per cent. | | | | | | | |
| Cholesterin, | Average | .438 | 2.56 | 1.47 | 2.54 | .628 | .795 |
| CaO | " | .360 | .614 | .688 | .496 | .537 | .437 |

Previous to death, the dogs were starved three to four days; those receiving injections were killed three to four days after.

The observed increase in cholesterin, which is especially pronounced in the case of the ricin series, depends partly on the presence in the bile

*A vegetable diet is supposed to diminish the bile-salts and a meat diet to increase them. It is uncertain, however, that these physiological factors assume pathological significance. It has also been thought that decomposition (putrefactive or fermentative) of the bile-salts in the cystic bile reduces the solvent action for cholesterin, but Minkowski showed that the cholalic acid thus liberated still possessed solvent action.

†Dott. F. E. Halia, Batteri Della Calculosi Biliare Coltivati Nella Bile, La Reforma Medica, Vol. II, N. 70, 1901. This observer found in filtered and sterilized ox-bile that colon bacilli and typhoid bacilli gave an acid reaction to bile which had been rendered alkaline. He regards these organisms as the specific exciters of cholesterin stones. The results obtained by Halia do not accord with those obtained by Dr. Dunham on human bile.

‡This conclusion was reached by Mr. Rettger from a careful study of pig's-bile.

*The difficulty in carrying out such experiments is considerable, owing to the insolubility of cholesterin in water and its resistance to saponification. It is impossible to insure prompt absorption from the intestine or from the peritoneum and intravenous injections of finely divided substance cause death from embolism. We have not succeeded in heightening the cholesterin content of the bile by experiments of this kind, but do not consider our experiments conclusive as to the question at issue.

†It is extremely probable that the converse is also true and that conditions causing an obstruction to the outflow of the bile lead to an increase in the cholesterin of the blood. This was claimed by Frerichs to be the case. Observations made in my laboratory but not yet completed point to the conclusion that this view is correct.

of cholesterin holding epithelia,* partly on an increased solution of cholesterin† (also of epithelial origin) in the bile. One would anticipate that under these conditions the bile would become saturated with cholesterin and thus prepare the way for the deposition of cholesterin from the bile, perhaps in crystalline form. Crystals of cholesterin were not observed in any instance among the remains of desquamated epithelial cells in the gall-bladder, but these negative results are not surprising if one considers the short duration of the experimental observations.

An increase in the cholesterin in the bile may be observed after slight mechanical injuries to the mucous membrane of the canine gall-bladder, after the intracystic injection of cultures of human colon bacilli, after phosphorus poisoning and after a prolonged diet of fat. Bacteria are certainly not essential to the production of the catarrhal inflammations which are attended with an increase in biliary cholesterin. I have several times found the bile to be sterile in mercurial and other inflammations excited by Dr. Wakeman.

*Cholesterin Content of Human Cystic Bile.*—At my request Dr. Helen Baldwin has made observations on the cholesterin content of the human cystic bile obtained from more than sixty autopsies. The results of her earlier analyses are given in the following table:

TABLE II.

Showing Cholesterin Content of Human Cystic Bile in Various Conditions (based on 40 autopsies).

| | | |
|---|---|---|
| Average of all the cases (excluding 8 cases of acute lobar pneumonia and 3 cases with cholesterin stones) | 0.13 | per cent. |
| Average in 6 cases of acute miliary tuberculosis (excluding one case with large cholesterin stones) | 0.167 | per cent. |
| Average in 12 cases of chronic nephritis | 0.20 | per cent |
| Average in 8 cases of acute lobar pneumonia | 0.248 | per cent. |
| Average per cent. solids of bile in 8 cases of acute lobar pneumonia | 11.7 | per cent. |
| Average per cent. solids of bile in 50 cases analyzed | 11.3 | per cent. |

There are some points connected with these figures that call for brief comment. In order to obtain strictly normal values for the cholesterin of human cystic bile one would be almost wholly restricted to the results found for biles obtained from healthy individuals who have died by accident. The average given in the table (0.13 per cent.) is based on a series of autopsies which include some instances of sudden death by accident, but which also include a large proportion of deaths from the ordinary causes. These autopsies include, for instance, the series on persons with chronic nephritis. There is consequently no doubt that the average obtained is too high for normal individuals, who would probably give a percentage not very far from 0.1. Nevertheless the comparison with the values found in other groups of cases is of interest.

The relatively high percentage (0.20) found for the 12 cases of nephritis is noteworthy and can hardly be regarded as accidental, although its interpretation is not yet clear. Possibly it depends on an increase in the cholesterin of the serum of the blood connected with the existence of widespread arteriosclerosis in these cases, but it may be due to local conditions in the gall-bladders dependent on the colon bacillus infection which is so common in persons with advanced nephritis. The bile from persons dead of chronic nephritis often contains a dark sediment of very small granules which seem to consist largely of cholesterin and some of which may possibly be the nidus of future gall-stones. The high percentage noted in the cases of pneumonia are also of interest although here again the interpretation of the results is difficult. Possibly the excessive cholesterin is connected with infection of the bile and bile-passages. It would certainly be interesting to know whether the liability to gall-stones is greater among persons who have had pneumonia than among those similarly conditioned who have not had the disease.

It is not unlikely that there are temporary infections of the cystic bile which lead to a temporary increase in cholesterin which gradually returns to normal after the subsidence of the infection.

The bile from gall-bladders containing cholesterin stones is certainly apt to contain an uncommonly high percentage of cholesterin. Thus in one instance the proportion reached 0.308 per cent., in another 2.42 per cent. On the other hand where pigment stones are present the cholesterin of the bile may not exceed 0.014 per cent.

*Calcium.*—Our knowledge of the calcium of the bile in health and in disease is rather less satisfactory than that which we possess respecting cholesterin. We know that the calcium content of canine cystic bile is normally from 0.050 per cent. to .090 per cent., whereas the percentage in

*In collecting the bile for analysis the loosely adhering cells were in every case (in both normal and pathological gall-bladders) gently removed with a dull spatula and added to the remaining contents of the gall-bladders.

†From experiments made by Mr. L. F. Rettger at the Sheffield Scientific School, it is probable that some general protoplasmic poisons are capable of increasing the cholesterin within the gall-bladder. Thus after a period of phosphorus poisoning of eight days' duration, Rettger found the gall-bladder of a rabbit studded with masses about the size of a pin-head, which responded to the chief tests for cholesterin. The bile was sterile. In three other rabbits, similarly treated, no such masses were found.

*Note.*—The following observations on the solubility of cholesterin in pigs' cystic bile are of some interest. The analyses were made by Mr. L. F. Rettger. Four portions of same bile, fresh and normal, were taken:

*a.* 100 c.c. unfiltered; amount of cholesterin..... 0.040 gm
*b.* 100 c.c. filtered through good filter paper; amount of cholesterin in filtrate..... 0.044 gm.
*c.* 100 c.c. frozen two weeks and filtered; filtrate thoroughly washed; amount of cholesterin..... 0.042 gm.
*d.* 100 c.c. inoculated with culture of human colon bacillus and incubated two weeks; cholesterin in bile ..... 0.036 gm.

Similar observations on normal bile filtered and unfiltered gave comparable results to (*a*) and (*b*).

100 c.c. of normal pigs' bile inoculated with culture of human colon bacillus and contaminated with an unrecognized putrefactive organism, was incubated for two weeks. No bile became putrid. Amount of cholesterin after putrefaction ..... 0.0365 gm.

This represents a loss of 0.0205 gm. during putrefaction (based on comparison with control).

The following observations relate to the influence of acid on the solubility of cholesterin:

Two portions of fresh pigs' bile were taken.

*a.* 100 c.c.; amount of cholesterin..... 0.0883 gm.
*b.* 100 c.c.; 3 c.c. normal HCl solution. Allowed to stand 4 days at room temperature. Filtered and residue thoroughly washed. Amount of cholesterin ..... 0.0781 gm.
(Difference=0.0102 gm.)

the blood is considerably lower.* We know also that the calcium content† of human cystic bile does not normally differ materially from that of canine cystic bile and is commonly below 0.10 per cent. Why the percentage of calcium in the bile is higher than that of the blood, and higher even than that of the serum, is not yet clear. It appears improbable that the difference is due to the absorption of water from the gall-bladder and it is more likely to be dependent on an actual addition of calcium to the cystic bile. This point could be settled by a comparison of the calcium of the blood serum with that of the hepatic and cystic bile in the same patient or experimental animal, but the necessary observations appear to be wanting.

A noteworthy thing about the cystic biliary calcium in pathological conditions is that it seldom varies greatly in percentage from that of normal bile. In this respect the calcium of the bile stands in marked contrast to the cholesterin. The comparative uniformity of the calcium values is observable both in experimental and human pathological conditions. Thus in the experimental inflammations of the gall-bladder, already referred to, the average calcium content of the bile was not greater than the average of the normal biles. This applies to the experiments with bichloride of mercury and to those with carbolic acid and ricin. (See Table I.) Increased cholesterin, however, is a feature of these experiments and has been commented upon already. This independence of the calcium and cholesterin of the bile is of interest when we consider the varying composition of gall-stones in respect to their constituents.

A moderate increase in the percentage of biliary calcium, or at least high values for calcium —was observed in some of the cases of experimental cholecystitis. The highest percentage observed in any case relates to one of the mercury experiments where the calcium reached 0.166 per cent. In the cases where the calcium appeared to be high no explanation of the fact has been evident. The calcium content of the blood serum in such cases was not ascertained.

In human pathological conditions, also, the calcium of the bile seldom shows any remarkable increase above the normal. The average calcium in Dr. Baldwin's‡ 40 observations was 0.072 per cent. Three times only was the calcium in excess of 0.120 per cent. Once it reached 0.272 per cent., once 0.214 per cent. and once 0.181 per cent. The solids in these instances were exceptionally high (17.7 per cent., 21.5 per cent. and 21.7 per cent.) but there is no close relationship between calcium and solids in the 40 observations regarded as a group. Neither is there any relation between the cholesterin content of these human cystic biles and their cholesterin. High cholesterins with low calcium are very common. High calcium with low cholesterin is less common but is sometimes a striking feature. Thus in a case of lobar pneumonia in which the calcium value was 0.272 per cent. the cholesterin was only 0.136 per cent. In 7 cases in which the calcium was in excess of 0.10 per cent. advanced chronic nephritis was present in 4 instances.

It should also be mentioned that in two cases in which the gall-bladder contained pigment stones the calcium content of bile was low, in one case 0.046 per cent., in the second 0.018 per cent. These observations suggest that a high percentage of calcium is not a prerequisite for pigment stone production, although there is no proof that the calcium of the bile was normal at the time when the stones were in process of formation.

What is the source of the biliary calcium in those cases where this element is present in excess? A satisfactory answer to this question cannot at present be given but there are several considerations which give at least a clue to the answer. The very high calcium percentage in the bile, as compared with the normal calcium percentage of the blood serum, in some pathological conditions, makes it unlikely that the excess of calcium comes directly from the blood into the hepatic bile. The widely held view that persons living in limestone districts are especially liable to gall-stones led Jankau to feed a dog large doses of calcium phosphate, neutral calcium phosphate and calcium lactate in order to determine whether the biliary calcium could be thereby increased. He obtained negative results. This experiment cannot, however, be regarded as establishing the doctrine that the calcium of the food (and hence of the blood) under no circumstances influences the biliary calcium. An increase in the calcium of the blood may be followed by a moderate increase in the calcium of the bile for Dr. Wakeman found the average calcium content of the cystic bile of 20 normal dogs to be equal to 0.077 per cent. of calcium oxide, whereas in the biles from 12 dogs intravenously infused with a calcium chloride solution* the average percentage was 0.886 per cent., and in one instance reached 0.152 per cent. which is distinctly higher than any normal observed. Although the experimental conditions were unlike any that arise in man these observations leave it an open question whether the calcium of the bile may not be somewhat increased if for any reason the calcium content of the blood is heightened. But it appears improbable that a considerable excess of calcium can be accounted for in that way and it is furthermore unlikely that concentration of the cystic bile is an important factor, even where the effects of concentration are added to those of a high calcium percentage in the blood.

*The following observations on the calcium of the blood and the cystic bile from the same dogs are not without interest.

| | Per Cent. | Per Cent. |
|---|---|---|
| Dog I. | CaO of bile.. 0.078 | CaO of total blood..... 0.0153 |
| Dog II. | CaO of bile.. 0.068 | CaO of total blood..... 0.0116 |
| Dog III. | CaO of bile.. 0.056 | CaO of total blood..... 0.0091 |
| Dog IV. | CaO of bile.. 0.044 | CaO of total blood..... 0.0091 |
| Dog V. | CaO of bile.. 0.068 | CaO of blood serum... 0.014 |
| Dog VI. | CaO of bile.. 0.056 | CaO of blood serum... 0.017 |

†In every instance where calcium is referred to in quantitative terms calcium oxide is meant.

‡Naunyn, Klinik der Cholelithiasis, p. 15, 1892.

*From 1 to 2 grams of calcium chloride were introduced in this way.

The view expressed by Gilbert that the biliary calcium is largely derived from the mucous membrane of the gall-bladder through its mucous and desquamated epithelium is probably in large part correct. The acid mucin is probably combined with calcium when it passes the mucus from the mucous glands into the cystic bile or into the hepatic bile. One would therefore anticipate that whenever there arises a catarrhal inflammation of the gall-bladder the conditions would become favorable for an increase in cystic calcium and hence for a precipitation of calcium salts. But so far as I am aware careful experimental data relating to this point are lacking.*

An excessive concentration of the biliary calcium is probably answerable for the deposition of salts of lime, especially calcium carbonate and calcium phosphate. Calculi containing such salts in abundance are sometimes found in cattle, and foreign bodies in the human gall-bladder may undergo incrustation with calcium salts. In true human gall-stones, however, the inorganic combinations of calcium are of less significance than the unstable and comparatively unstudied organic compound known as bilirubincalcium.†

The conditions under which bilirubincalcium separate from the human bile to enter into the composition of calculi are only imperfectly understood and deserve painstaking study, since bilirubincalcium is so common a constituent of gall-stones. Naunyn showed that mere concentration of the bile, at least in the case of dogs' bile, does not suffice to bring about the separation of bilirubincalcium. Observations already referred to in this paper render it improbable that increased concentration of calcium salts necessarily occasion precipitation. If other conditions are operative separation may occur when the calcium content of the bile is not excessive. This inference seems to be justified by the fact that one may discover bilirubincalcium in the sediment of human bile in the absence of an unusual percentage of lime. An important factor in favoring precipitation is the reaction of the bile. A pronounced alkaline reaction to litmus facilitates separation. Still we do not know how frequently this factor comes into play in the production of human biliary calculi. Finally, it is known that the presence of proteids may exert a powerful effect in determining a deposition of bilirubincalcium from the bile. Variations in the biliary proteids may thus come to assume importance for the pathogenesis of calculi. It belongs to future investigations, however, to establish the conditions under which the proteids of the bile play a part in causing the precipitation of bilirubincalcium. It seems not improbable that this precipitation will be shown to depend on the cooperation of several variable influences, the efficacy of a single factor, such as alkalinity, being commonly dependent on associated conditions.*

*Relation of Bacteria to Gall-stone Production.*—It has been shown that the chief constituents of gall-stone, cholesterin, and bilirubincalcium, have their origin in local alterations of the mucous membrane of the gall-bladder involving desquamation of epithelium on the one hand, and probably an increased production of mucus by the mucous glands, on the other. Hence it is appropriate to inquire into the causes of these local alterations, which are the common accompaniments of cholecystitis.

*Bacterial Origin of Cholecystitis.*—Modern studies make it clear that the various forms of cholecystitis are in almost all instances of bacterial origin. The chief inciters of the inflammatory process are *Bacillus coli communis, Staphylococcus albus, Staphylococcus aureus, Streptococcus pyogenes, and Bacillus typhosus.* Frequently one type of organism is obtained in pure culture from the bile, but at times two or more varieties are found in association. The character of the alterations in the walls of the gall-bladder and in the bile depend on the nature of the organisms and their degree of virulence. The chemical characters of the bile, as influenced by these different conditions, have not yet received the attention they deserve. Some characteristic relations have, however, been noted, which are worthy of mention. Thus the cystic bile in the typhoid infection of the gall-bladder, so commonly found in typhoid fever, is increased in amount, watery, dirty brown in color and contains an abundance of epithelial cells and epithelial detritus. A mild cholecystitis is present in such cases although it commonly happens that there are no distinct symptoms referable to the gall-bladder. The occurrence of so much desquamated epithelium is suggestive of a rich source of cholesterin, and it would be well worth while to actually determine the cholesterin in a series of such typhoid biles.

The relation of cholecystitis to gall-stone formation is strikingly shown by a table of 32 cases of typhoidal cholecystitis compiled by Ehret and Stolz ‡ which were either subjected to autopsy or came to operation. In 20 of these 32 cases gall-stones were present! This is of course a very high proportion as compared with the percentage observed in autopsies made at random on persons of the same age and sex.‡

From what we know at present of infectious cholecystitis it is safe to say that such processes

*This point can probably be settled experimentally by means of poisoning by toluylendiamine, since this substance markedly increases the mucus of the bile, even in the small hepatic ducts.

†Bilirubincalcium can be precipitated by the addition of calcium chloride to an ammoniacal bilirubin solution. It forms a rust-colored flocculent deposit which has a metallic green luster when dried over sulphuric acid. It is a definite compound, in which bilirubin behaves like a monobasic acid, and is represented by the formula $(O_{16}H_{17}N_2O_3)_2$ Ca. It is insoluble in water, alcohol, chloroform and ether. A corresponding sodium compound can be prepared.

*It is said that the presence of bile salts tends to prevent the combination of bilirubin and calcium (Brockbank). Another factor which may influence precipitation is the quantity of bilirubin in the bile. It is especially desirable that the influence of mucin and of albuminous inflammatory exudates should be studied.

‡Experimentelle Beiträge zur Lehre von der Cholelithiasis Mitt. aus der Grenzgeb. der Med. u. Chirurgie, Bd. VII, 2. and 3. Heft, S. 372.

‡It is noticeable that the average age of these patients with typhoid cholecystitis is less than twenty-eight years.

afford conditions favorable to the production of cholesterin and mucus in excess, although we do not yet know under precisely what conditions their overproduction is most likely to happen. It seems probable from experimental data that infections of a moderate or slight degree of virulence are most likely to result in conditions favorable to gall-stone production, a supposition which accords well with the frequent absence of a history of acute cholecystitis preceding symptoms of gall-stone colic.

*Occurrence of Bacteria in Gall-stones.*—It has now come to be generally admitted that a large proportion of gall-stones from the human subject contain bacteria in their centers, sometimes living, sometimes uncultivable. M. Galippe* apparently deserves the credit of initiating the investigations which have led to this important conclusion. In 1890, about four years after the publication of Galippe's first paper, Welch found the *Bacillus coli communis* and the *Staphylococcus pyogenes* in gall-stones and since that time the subject has been studied by Gilbert and Dominici,† Gilbert and Fournier,‡ Hanot,§ Létienne‖ and others. The *Bacillus coli communis* and the typhoid bacillus have been the organism most frequently found.¶

No careful and extended studies have yet been made with a view to determining whether there is apt to be a relationship between the nature of the bacteria derived from gall-stones and the chemical constitution of the stones. There is some reason to think that pure cholesterin stones are often associated with a nucleus which contains colon bacilli, and it has been claimed that the *Streptococcus pyogenes* is apt to be associated with stones rich in calcium salts.

*Experimental Production of Gall-stones.*—The mere presence of pathogenic bacteria in the centers of gall-stones, though a fact of much interest, is far from being a proof of the micro-organic origin of biliary calculi. If, however, it could be shown that the experimental introduction of such bacteria into the gall-bladder, under suitable conditions, is often followed by the formation of gall-stones hardly distinguishable from human calculi as regards constitution and bacterial contents, this would constitute an indestructible prop to the doctrine that bacterial infections lead to the production of calculi. Efforts to induce gall-stone formation in this manner were for a long time unrewarded by success. In 1897, however, both Gilbert and Fournier* and Mignot† reached the important goal for which they had striven, and obtained definite calculi by infecting the gall-bladder with the *Bacillus coli communis.*‡ It was soon afterward shown that true biliary calculi very closely resembling those found in human gall-bladders, as regards form, color, stratification and bacterial contents, can be experimentally induced through infection with *Bacillus typhosus.*

This result is of the first importance to gall-stone pathology, for it has brought a knowledge of the leading conditions requisite for the production of calculi through infection.

*The Conditions of Calculus Production From Infection.*—(*a*) Degree of Virulence of Micro-organisms. The mere introduction of virulent micro-organisms into the gall-bladder of an experimental animal does not usually suffice to induce gall-stone formation. Such organisms generally set up an acute cholecystitis and the very severity of the process defeats the desired end by causing destructive or atrophic alterations in the mucous membrane of the gall-bladder, that lead to interferences with the continued overproduction of cholesterin underlying calculus formation.

If, however, the infective agent be first attenuated in virulence, as suggested and practised by Mignot, the chance of inducing stone formation is very greatly increased. This is apparently for the reason that bacteria attenuated in virulence set up a subacute cholecystitis peculiarly favorable to the establishment of cholelithiasis. A further precaution which helps to insure success in causing experimental cholelithiasis is the cultivation of the bacteria employed, in diluted bile, during several weeks before their introduction unto the gall-bladder. This procedure appears to facilitate the adaptation of the bacteria to the normal bile, by which they secure a permanent foothold in the gall-bladder.

As to the kind of organisms capable of inducing gall-stones Mignot's work shows that *Bacillus coli, Bacillus typhosus, Staphylococcus pyogenes, Streptococcus pyogenes* and even *Bacillus subtilis* may each be successfully employed as inciters of gall-stones. But their degree of virulence appears much more significant in this connection than the variety of micro-organism. (*b*) Retention of Micro-organisms in the Gall-bladder. It is obvious that an essential condition for experimental gall-stone production is the retention of the living infective agents within the gall-bladder. Two natural defenses of the normal organism are constantly opposed to the es-

*Galippe's very suggestive paper is entitled Mode de Formation du Tartre et des Calculs Salivaires: Considérations sur la Production des Calculs en général; Présence des Microbes ou de leur germes dans les Concrétions (Journal des Connaissances Médicales, 25 Mars, 1886).

¶Only intact calculi should be bacteriologically studied as the lightest abrasion permits the entry of intestinal bacteria. Calculi covered with a pigmentary stratum are impervious to bacteria, but pure cholesterin stones, without such protection, are liable to permit the invasion of intestinal bacteria after death.

*Gilbert, A. Note pour servir à l'histoire de la theorie microbienne de la lithiase biliare, Archives Générales de Médicine, Vol. II, p. 257, Septembre, 1898. Gilbert was put on the path leading to success through observing in conjunction with Dominici (Angiocholite et cholécystite typhique expérimental, Comptes Rendus de la Soc. de Biologie, 23 Décembre, 1893, p. 1033) in 1893, that little concretions ("petites concrétions verdâtres") formed in the gall-bladder of a rabbit with typhoidal cholecystitis. After this methodical attempts were made to obtain more typical concretions.

†Reported at the Société de Chirurgie, May 19, 1897. See Hartmann, M. H., Pathogénie de la Lithiase, La Presse Médicale, No. 10, 2 Mars, 1898, p. 111.

‡The priority in this work belongs to Gilbert, although Mignot made the first public announcement of his results. See Cushing, Johns Hopkins Hospital Bulletin (Nos. 101 and 102) p. 168, 1899. Cushing, Richardson and Lartigau, in this country, have each succeeded in producing calculi by infecting the gall-bladder.

tablishment of bacteria in the gall-bladder. One of these depends on the fact that the bile (at least in the case of dogs) is a poor medium for the multiplication of certain kinds of bacteria and when fresh is not in general an ideal basis for bacterial growth. While it is very doubtful whether even quite fresh bile has any antiseptic action the relatively slow multiplication of intestinal bacteria in this medium (as compared, for instance, with bouillon) during the first hours after infection, must operate as a protection against injury from micro-organisms, provided the bile has a free exit and is not permitted to remain many hours in stagnation. In health there is a free exit both for the cystic and the hepatic bile and the normal bile current into the duodenum is such as to constitute a most effective defense against the domicile of bacteria within the bile-passages. It is easy to satisfy oneself of the importance of this normal bile outflow by injecting bacteria of moderate virulence into the gall-bladder, where they fail to gain a foothold. The outcome is, however, greatly altered if one first ties the cystic duct or detains the micro-organisms by means of foreign bodies to which they cling. Mignot made effective use of the latter method. In one set of observations these foreign bodies, impregnable with the bacteria to be tested, were permitted to sojourn in the gall-bladder during the entire period covered by the experiments. In another series the foreign bodies were removed by operation after a lapse of three or four weeks, during which time the bodies were operative in keeping bacteria in contact with the mucosa, thus facilitating the establishment of a cholecystitis. In both sets of observations the animals were killed after four or five months and the gall-bladders were found to contain concretions comparable with human calculi, chemically, physically and bacteriologically. Some of the stones resembled the pure cholesterin stones of man. A few contained some sodium chloride and some bile-acids and bile pigments.

*The Influence of Foreign Bodies.*—The observation that various foreign bodies* have occurred in the centers of human gall-stones has led some writers to attach considerable importance to these accidental inmates of the gall-bladder, as inciters of stone production. If, however, we leave out of consideration the epithelial masses (which cannot be classed as foreign bodies) and the masses of bacteria so often discovered at the centers of gall-stones, definite foreign bodies are rare constituents of calculi. Nevertheless it is interesting to consider for a moment what influence foreign bodies have upon the separation and crystallization of the constituents of calculi. It is certain that sterile glass beads and similar bodies can be left in the gall-bladder of an animal for many months without occasioning the formation of any concretions.† This negative result can not, however, be interpreted to mean that foreign bodies are always without influence upon the production of calculi, for it is undeniable that just in so far as they interfere with the complete expulsion of the cystic contents do they favor the accumulation of micro-organisms in the gall-bladder. In this way human gall-stones may become operative in facilitating reinfection of the gall-bladder at any time after the death of the bacteria to which they owe their birth. It is interesting that even a stone with a smooth surface facilitates the retention of bacteria in the gall-bladder on account of the layer of fluid which clings to their surface owing to the operation of capillary attraction. Porous stones one would expect to be even more effective owing to their impregnation with bacteria.

*The Influence of Mechanical and Chemical Irritants.*—Experimental damage to the walls of the gall-bladder by heat (cauterization), scratching, and the application of silver nitrate was found by Myake to be without influence in causing infection. The bile remained sterile in all experiments of this kind. In my laboratory we have had a similar experience with injections of mercuric chloride. These results are, of course, no evidence that chemical irritants causing an excess of cholesterin in the bile might not in time lead to the production of gall-stones even in the absence of infection. On the other hand, there is at present no unimpeachable evidence for the view that stone formation occurs independently of infection, where the stone-forming elements of the bile are increased.

*The Micro-organisms of Normal Bile.*—The not inconsiderable literature relating* to the bacteriological examination of the normal bile of dogs, rabbits and guinea pigs indicates that in a majority of instances the bile is sterile, at least so far as can be judged by the ordinary methods of examination, in which small quantities of bile are employed in making cultures. Observations made at my suggestion by Mr. L. F. Rettger are in harmony with this view. Rettger made cultures from the bile from six normal dogs, with negative results in every instance. Smears made with the bile taken from the gall-bladders of 32 normal pigs showed growths in only three instances.† That the bile of guinea pigs and of rabbits is ordinarily free from pathogenic organisms is made probable by experiments of Fraenkel and Krause,‡ in which they snipped the gall-bladders and permitted the bile to run into the peritoneal cavity without causing infection.

These various results cannot be regarded as absolute proof that the bile is strictly sterile in most instances, for it was found by Ehret and Stolz that the contents of the gall-bladder was

*Among the bodies noticed have been silk and metal ligatures, globules of mercury, a pin, clots of blood, etc.

†See Ehret and Stolz, also Mignot. A sterile silk thread may in time become encrusted with calcium salts, although the bile remains sterile, but it is doubtful if foreign bodies ever lead to a precipitation of bilirubin or cholesterin.

*Zur experimentellen Erzeugung der Gallensteine mit besonderer Berücksichtigung des bakteriellen Verhalten der Gallenwege, Mitt. aus der Grenzgeb. der Med. u. Chirurgie, Bd. 6, 4. and 5. Heft, S. 479, 1900.

†In one case the colon bacillus, in a second the colon bacillus and an unknown coccus, in the third case one unidentified bacillus, probably a member of the colon group.

‡Fraenkel and Krause, Zeitschrift für Hygiene, Bd. 32, 1899, pp. 77 to 110.

infected in almost one-half the animals examined by them. These observers made their cultures with relatively large quantities of bile, thus increasing the chances of discovering bacteria. It may be safely stated, however, that the bile of normal dogs, pigs, rabbits and guinea pigs commonly is sterile or contains very small numbers of bacteria (usually members of the colon group).

Very similar conditions prevail in the case of human bile studied at autopsy. Although most of the patients examined by Fraenkel and Krause had died either of acute infectious diseases or with tuberculous lesions, the bile was sterile in 105 out of 128 examinations from the same number of patients.

It is notable, however, that although the bile of 34 out of 36 tuberculous patients was sterile by ordinary culture methods, the bile excited tuberculous lesions in 5 of the 11 guinea-pigs into which injection of the bile was made. It is thus not unlikely that micro-organisms are present in human bile more often than one might suppose from the results of cultures made with single supplies of bile. Even the bile of normal persons may be more often infected than has usually been supposed, but the organisms are probably neither numerous nor virulent in the majority of instances.

*Frequency of Human Biliary Infection in Disease.*—It is a well-established fact that even in the absence of cystic disease bacteria are likely to be present in human bile when there exist pathological conditions in parts remote from the gall-bladder. The *Bacillus coli communis* and the *Staphylococcus* are among the most common inhabitants of the bile under these circumstances. Other pyogenic cocci, including the *Pneumococcus*, are probably much less often present in the gall-bladder, at autopsies made at general hospitals on patients who have not had gall-bladder disease.

Some kinds of infective agents are easily missed, on account of the difficulty in making them grow on ordinary media. This is certainly true of the *Pneumococcus* and the experience of Fraenkel and Krause with the *Bacillus tuberculosis* makes it likely that this organism is often overlooked. On the other hand the presence of bacteria in the bile at autopsy is frequently to be regarded rather as the evidence of a terminal infection than as the expression of an earlier invasion.

(To be Continued.)

**Banti's Disease.**—A case of the peculiar symptom-complex known as Banti's disease, developing directly after a severe trauma to the splenic region, is reported by D. Fichtner (Münch. med. Woch., Aug. 11, 1903). The view that the condition is only a manifestation of hereditary, tardy syphilis is gaining more and more ground, though it is often hard to obtain a history of syphilis in the parents and the patients only rarely show other signs. The author's case presented all the typical symptoms and in addition, went through a facial erysipelas complicated by a suppurative otitis media.

## THE MODERN TREATMENT OF THE ACUTE SUPPURATIONS OF THE KNEE-JOINT.

BY ARPAD G. GERSTER, M.D.,
OF NEW YORK;
SURGEON TO MOUNT SINAI HOSPITAL.

Etiologically, the acute purulent inflammations of the knee-joint can be divided into three groups. To the first belong the metastatic suppurations observed in infants shortly after the detachment of the stump of the cord, and in women during the puerperal period. But they are not rare in any form of pyemic fever, be its cause otitis media, or osteomyelitis or gonorrhea, or in fact, any conceivable order of suppuration, in which septic thrombi become detached and are carried into the portal or systemic circulation.

The second group is composed of cases in which the purulent infection of the joint is due to a direct perforative extension of the pyogenic process from an adjoining focus of suppuration as of an acute or chronic osteomyelitis.

The third group contains cases in which the septic infection is carried to the joint by a penetrating traumatism, laceration, stab, incision, or gunshot, either directly into the main articular space, or indirectly, through one or another of the accessory synovial bursæ. Such are the quadriceps bursa, the bursæ found underneath the semimembranosus, and those of the popliteal space, most of which have an open communication with the knee-joint.

We observe remarkable differences in the destructiveness and virulence of the various forms of acute pyarthrosis. The metastatic suppurations have the mildest character. Next in virulence stand the suppurations communicated from an adjoining focus of infection. The most dangerous are those due to traumatic infection. While in these, by the intense sepsis, limb and life of the patient are placed in jeopardy; the former, unless neglected, will rarely do other lasting damage than a more or less complete disability of the joint.

When the initial sepsis does not destroy the patient's life, and no steps are taken to relieve the process by surgical measures, we see that the thickened and congested synovial capsule will be eroded and perforated. With this a certain quantity of the septic contents of the joint will escape into adjoining areolar spaces, and the enormous intra-articular tension being somewhat relieved, the local and general symptoms will show a certain abatement. But this improvement is temporary only, lasting not longer than the time required for the tense repletion with pus of the secondary abscess or abscesses. These, in turn, will break down intervening barriers, the suppuration extending along the lines of least resistance upward into the thigh, or downward, following the areolar planes of the muscles and tendons of the leg.

Exceptionally, when the perforation of the synovial membrane corresponds to the anterior or lateral aspects of the joint, where the abscess becomes at once subcutaneous, the integument may

be perforated also. Thus a short fistula may be established, leading directly into the joint cavity.

But the destructive action of the septic process is not limited to the capsule alone; it involves the cartilaginous joint surfaces also. These become discolored, roughened, and separated from the underlying epiphysis in the shape of smaller or larger irregular tatters. This loss of the articular cartilages is the cause of the subsequent anchylosis.

The diagnosis rests mainly upon the proof of the facts, that the joint is distended by an exudate, and that the distending material is pus. We need not dwell upon the physical signs of distention of the knee-joint. The change from the normal shape of the joint to that characteristic of a distended joint, the presence of fluctuation and of ballottement of the patella will suffice. Where such distention is accompanied by intensely septic general symptoms of growing severity—even to the so-called typhoid status—when, at the same time, the local disability, tenderness to touch, the exquisite pain and the edema of the integument all point to a destructive process, the crucial question of "pus or no pus" should be immediately put by means of the aspirating needle.

Errors of diagnosis are rare in pyemic or in traumatic cases, more common, however, when the joint suppuration is due to perforation from an adjoining focus of acute osteomyelitis. Of diagnostic errors that have come under my personal observation, that of acute articular rheumatism was the most frequent one, then followed cerebrospinal meningitis, and finally typhoid fever. A careful and systematic going over of the whole body of the patient, especially when he is more or less comatose, will soon establish the presence of the characteristic, pale and deep-seated edema of the lower end of the femur or of the upper end of the tibia. Pressure over the epiphysial line will not fail to elicit signs of distress, even in a deeply comatose patient, and the practitioner, if his diagnosis be made early, will at this stage find no abnormality about the joint.

Let us now enter into a separate study of the three groups above defined.

*1. Metastatic or pyemic suppuration.*—Ordinarily the onset of this trouble is mild, its course inclined to be chronic. The local symptoms are not very salient and are often obliterated by those of the general condition, so that they may be overlooked both by patient and physician. Occasionally, however, they will be very acute and obtrusive. The mildest infantile forms show even a tendency to spontaneous cure, and ought not be meddled with. They occur frequently during and after puerperal fever, accompanied by purulent collections in other joints, and as before mentioned, in the new-born, at the time of the separation of the umbilical cord. If the local symptoms are troublesome they will demand surgical interference. First evacuation by puncture, and if the collection be ropy and thick, by irrigation. Rapid reaccumulation will demand incision and drainage. The number of incisions must depend upon the acuteness of the local symptoms. In mild cases two lateral incisions, placed along the sides of the patella, and a median incision penetrating the quadriceps bursa will be found sufficient. A rubber tube is placed into each one, and the dressed limb is fixed on a suitable splint, preferably in horizontal suspension. Daily change of dressings and irrigation will follow. As soon as the secretion becomes serous, the tubes ought to be withdrawn. In small children, one, or at most, two incisions will suffice, and here the use of carbolic solutions is strictly to be shunned on account of their highly poisonous influence. In infants, the function of the joint is commonly restored, but this is not exceptional in puerperal cases, especially when they have received prompt and adequate attention. One of the most troublesome forms of metastatic infection of the knee-joint is that due to gonorrhea. Ordinarily it appears in the shape of gonorrheal rheumatism; the places of predilection being the wrists and the knee-joints. The exudate is rarely copious, and the lack of harmony between the moderate physical signs and the exquisite painfulness one of the paradoxes of surgical experience. Only those cases will require active interference in which massive effusion and great tension threaten the integrity of the joint. The course of the malady is very slow and rebellious, but in the majority of cases, the function is restored.

*2. Suppuration due to osteomyelitis.*—Osteomyelitis is eminently a disease of adolescence, being most frequent in the years just preceding puberty. In the lower extremity the place of predilection is the neighborhod of the knee-joint, or more precisely, the lower epiphysial line of the femur, or the upper one of the tibia. In children, the epiphysis itself does not represent a great mass, and, therefore, it is not rare, that having become the seat of osteomyelitis the process extends to the epiphysial cartilage. For a short while this acts as a barrier against the spread of the infection; but as soon as the necrosed part of the cartilage is loosened and flakes off, pus pours into the opened joint and we have to deal with a suppurative gonitis complicating the osteomyelitis. This is the most common form of causation.

At other times, the osteomyelitis having produced an abscess involving the soft parts of the extremity, this abscess, especially when situated in the popliteal space, may perforate into one of the popliteal bursæ which freely communicate with the joint; or, a direct perforation from without inward may occur through the synovial capsule. In all these cases the osteomyelitis must have existed for some time, the involvment of the knee-joint being a late complication. On the other hand, where the osteomyelitic focus penetrates directly into the joint, we see the symptoms of acute osteomyelitis and of acute gonitis compounded and overlapping. In every case of osteomyelitis attacking the tibia or femur near the knee, it will be the duty of the practitioner to watch the joint and not to overlook an effusion

distending it. But the edema of the integument caused by the osteomyelitis, should not be mistaken for an effusion, which must present the classical signs of fluctuation and ballottement. Flexion and rigidity of the joint, being regular companions of osteomyelitis, have also an inferior diagnostic significance.

According to modern ideas, every osteomyelitic focus ought to be freely opened as soon as the diagnosis is made. A free external incision will expose the bone, and the chisel and mallet will lay open the diseased medulla and cancellous tissue. Thus, in favorable cases, the extension of the infection to the articular cartilage may be averted. But where the joint has been attainted, the osteomyelitic focus ought to be followed up and traced to where it perforated the cartilage. To this should be added at once arthrotomy.

In speaking of the treatment of the pyemic forms of gonitis, we have already mentioned the methods of multiple arthrotomy found to be adequate in that class of cases. Experience had taught us, that in virulently septic gonitis two lateral incisions, supplemented by an incision into the quadriceps bursa, did not afford effective drainage. And this is easily understood if we consider the irregular and sinuous conformation of the knee-joint. Hence we saw that Andrews, of Chicago, proposed to make five drainage apertures; one into the quadriceps bursa, two laterally above and two below the patella. Sometimes this proved to be adequate, often, however, insufficient, and the author of this paper, together with other surgeons, sought to render drainage still more perfect by entering the joint posteriorly, through the popliteal cavity, that is at its most dependent portion. The exposure of the capsule in this region, demanded, of course, on account of the popliteal vessels, careful preparatory dissection. This also was found to be unsatisfactory, the reason being, first, that the infection did not concern the surface of the synovial membrane alone, but involved its entire thickness, together with more or less of the underlying tissues; and, secondly, that drainage and irrigation of the complicated joint cavity could never be made perfect by means of multiple incisions.

Mayo, of Rochester, Minn., finally proposed and successfully employed a radical procedure, possessing the greatest value, and which has been deservedly accepted by the surgical fraternity. It consists of the transverse incision of the infected knee-joint, passing from condyle to condyle just above the patella, and, of course, dividing the quadriceps tendon. Ollier, the French surgeon, supplemented Mayo's incision by advising the extirpation of the crucial ligaments.

The advantages of Mayo's incision are manifest. The joint having been widely opened along three-quarters of its circumference, direct access to all its recesses becomes easy, especially if the crucial ligaments be also divided. Each of the sinuosities of the capsule can then be inspected and subjected to direct local treatment by packing. To do this thoroughly, the knee is flexed to an angle of 45°, and after due packing is dressed in this position. Experience has taught us the great advantage of this treatment over irrigation, even if permanently employed. The contact of the medicated packing with the diseased capsular tissues favors profuse exudation, by which they are rapidly depleted of infectious matter. Ordinarily, the local and general septic symptoms rapidly subside, and within a week or ten days, the flexed joint can be again extended, in which position it is permitted to heal. Where most or all of the articular cartilage was preserved, even a certain degree of the function of the joint may be regained. Extensive loss of the cartilages, however, must end in firm anchylosis.

Experience enables me warmly to recommend Mayo's incision, where the virulence of the infection threatens the loss of the patient's limb and life. To illustrate its effect, the history of a typical case may here be quoted.

Yette G., thirteen years old, admitted April 8, 1902, to Mt. Sinai Hospital. Two weeks before admission she sustained, by a fall, an injury to the left lower extremity. Ever since then she was unable to walk. During the last four days she has had a number of severe chills followed by high fever. On admission considerable swelling extending from the hip to the knee was found, which was rigidly flexed. The joint, especially the quadriceps bursa, was much distended and exquisitely painful, the patella floating, and marked tenderness was observed along the lower epiphysial line of the femur. Temperature, 104° F., pulse 130. The diagnosis of acute osteomyelitis with involvement of the knee-joint being made, an immediate operation was decided upon. Aspiration of the knee-joint yielded pus. It was laid open by a transverse incision extending from epicondyle to epicondyle, and dividing the ligamentum patellæ. A large amount of thick pus was evacuated. The synovial membrane was found to be very edematous, with a reddish brown discoloration, the articular cartilages smooth and yellowish in color. The quadriceps bursa was also distended with pus, its synovial lining edematous and hemorrhagic. After a thorough cleansing and packing of the joint cavity, the lower extremity of the femur was exposed by an external longitudinal incision. The periosteum having been raised, the medullary cavity of the shaft and the cancellous tissue of the epiphysis were exposed by a fenestrum made with the chisel and mallet. In a well-defined area, they were found to be filled by pus and liquid fat. Spreads of the pus contained staphylococcus. This purulent area was removed by means of a scoop, and the resulting cavity was packed. The limb was dressed in the flexed position. Immediately the temperature and pulse rate began to descend, slowly but steadily. The dressing became rapidly permeated by a copious sanguinolent discharge, and its external portions had to be changed very frequently. By April 13 the morning temperature had fallen to 100° F., the evening temperature being 102° F.; the pulse about 100. The

deep dressings were then changed. The synovial membrane presented a clean, granulating surface, no retention was present. The osteomyelitic cavity also showed healthy granulations. The limb was extended, and the recesses of the knee-joint as well as the bone cavity were lightly packed, after which the extremity was fixed upon a dorsal splint. April 19 the flap containing the patella was sutured back into its normal position. By the end of April all the febrile symptoms had disappeared, and the cavities began to close up. June 30, all the wounds were healed, and mobility of the joint began to assert itself within an arch of 10 degrees. Presumably this would increase in due course of time. July 5 she was discharged cured. Walks well and is in an excellent general condition.

In my student days, along the late sixties of the past century, an acute septic suppuration of the knee-joint was considered as one of the fixed indications for amputation of the thigh. The excellent results of Mayo's incision have certainly helped to restrict the scope of this indication more than any previously known measure, but have not obliterated it completely. The following history will prove the fact:

Elsie L., twelve years old, admitted to Mt. Sinai Hospital, November 1, 1901. Nine days before this she had a fall, injuring her right leg, but was able to walk home. Two days later severe pains set in at the right knee with repeated chills, very high fever, much vomiting and great prostration. On admission we found her internal organs normal, right knee was rigidly flexed, but showed no signs of distention. The upper end of the tibia was the seat of a considerable amount of deep-seated edema. Fluctuation was also made out. The integument was pallid and shining. This edematous area was the seat of excruciating pain and extremely tender to the touch. Temperature, 104.2° F., pulse 140. The patient was immediately anesthetized, and the external abscess was widely opened. A ragged opening in the periosteum was found to lead into a large subperiosteal cavity extending downward to the middle of the tibia. The periosteum being raised, the chisel and mallet exposed the interior shaft and upper epiphysis of the tibia, which was filled with pus. The epiphysial line showed beginning purulent separation. Drainage of bone and external abscess and fixation of limb. Culture of the pus yielded staphylococcus. An immediate improvement of the general condition followed, though the patient continued to be feverish in the evenings. On November 16 the temperature rose to 103° F. An effusion appeared in the knee-joint, which, on aspiration yielded turbid synovial fluid. A thick trocar was inserted, and the joint was thoroughly irrigated with saline solution, then flushed with a 5-per-cent. solution of carbolic acid, and again washed with salt solution. For a few days the fever subsided somewhat, but soon became high again. The knee remained excessively painful. The tibial shaft showed a good tendency to granulate, but the epiphysis threatened necrosis. This led us to expect its perfect detachment, which became evident by Nov. 30. The child began to look markedly septic and aspiration of the knee yielded thick pus. Consequently, the joint, being incised according to Mayo, a certain quantity of pus was liberated. Three perforations of the articular surface of the internal tuberosity of the tibia were found. The quadriceps bursa also was distended by pus and had to be incised. The necrosed portions of the epiphysis were removed by means of the gouge, all the cavities were packed, and the limb put up in flexion. These steps were also followed by a passing and short improvement, but the gradual and complete necrosis of the epiphysis could not be arrested. The continuous fever, the copious discharges and the pain began to sap the strength of the patient, her liver enlarged, the pulse became very rapid and feeble, hence, to save her life, on Jan. 7, 1902, amputation in the middle of the thigh was done. Patient was discharged cured on Feb. 19, 1902.

Chronic ulcerative osteomyelitis, the common sequela of acute osteomyelitis, may also lead to perforation of the articular cartilage and to acute suppuration of the knee-joint. In one of the writer's cases (Wm. Kaplan, admitted May 10, 1898), this accident occurred ten years after the first attack of the acute disease. Originally a large sequestrum of the femur was extracted. The wound healed, and limb remained sound for five years; then, within the last five years it was operated upon for relapses four times, all involving the epiphysis, of which finally not more than a shell was left behind. May 13, the fifth time the cavity in the epiphysis was curetted. On May 30 suppuration of the knee-joint became manifest. June 2, Mayo's operation was performed. The articular cartilage was found to be extensively necrotic, together with the underlying remnants of the epiphysis. It became evident that the limb would be useless after the loss of the entire epiphysis. And as its remnants continued to necrose, this process maintaining an exhausting septic fever, amputation was done on June 23. On July 23 patient was discharged cured.

*3. Traumatic Suppuration.*—The author's first acquaintance with this dreadful form of infection was made in 1878. The patient was an old lady of about seventy years, who was much annoyed by a swelling occupying the inner aspect of one of her knees. The family attendant, an enterprising young practitioner, had correctly diagnosticated a chronic inflammatory distention of the bursa found underneath the semimembranosus tendon. In those days Fergusson's surgery was one of the accepted text-books, and our confrère went to this author for guidance. Fergusson recommended for curing bursitis or a ganglion, the drawing of a *seton* through the offending sac. For 36 hours the seton had caused little trouble, but then the bursa became infected, and rapidly the contamination spread to the knee-joint, with which the bursa had an open communication. The present writer stepped into the case at this stage of the malady, finding a thoroughly septic old

woman suffering from far gone arteriosclerosis and a fatty heart, having albumin, casts and sugar in her urine, the knee-joint distended with pus, the pulse rate and temperature very high, the patient failing. Incisions, irrigation and drainage were immediately resorted to, but without avail. The synovial lining of the joint was found extensively necrosed, and the patient succumbed within forty-eight hours after the onset of the gonitis, under the symptoms of combined sepsis and diabetic coma.

It may be justly remarked, that in this instance senile decay, chronic nephritis and the diabetes had as much to do with the fatal issue as the infection. But the following histories will demonstrate that traumatic infection of the knee-joint is a terrible enemy even under the most favorable conditions of general health.

Mrs. Alice H., thirty-eight years old, a butcher's wife, admitted March 14, 1897. Forty-eight hours before admission she fell, while holding an open penknife in her hand, and the narrow blade of the knife penetrated the knee-joint, from which synovial fluid had since then been escaping. She tied a wet rag to the knee, and went about her business. Six hours after the accident the joint became painful and a furious chill and high fever set in. When seen by the writer the joint was distended to the utmost. Just above the patella and corresponding to the internal margin of the quadriceps tendon an incised wound of about one-sixth of an inch in length could be observed. Its margins were reddened, swollen, and from the patulous orifice purulent synovial fluid was escaping at the slightest pressure. The temperature was 103.4° F., the pulse 120; the general signs were those of a profound sepsis. The tongue had become dry and was covered with a brown coating, the patient was somnolent, and vomited most of what she had unwillingly swallowed, and the expression of her face was indicative of great prostration. She was immediately sent to the hospital, where the joint was incised and drained. Two lateral incisions were placed above, two below the patella, and a fifth one directly into the quadriceps bursa. The limb was placed in suspension on a dorsal splint, and the drainage tubes were connected with two irrigators filled with Thiersch's solution, which was passing in a steady, slow stream through the joint. These comprehensive measures had not the slightest effect upon the general condition of the patient, who became profoundly comatose, her temperature rising to, and remaining above 105° F. The heart began to show signs of failure in spite of energetic stimulation. During March 15 30 cubic centimeters of streptococcus antitoxin were injected in three equal doses every six hours, without the slightest appreciable effect. March 16 the urine became loaded with albumin, hyaline and granular casts. A copious saline infusion and another administration of antitoxin did not retard the patient's death, which took place at about midnight; that is just four and a half days after the injury. The entire synovial membrane had become necrosed, and it is very doubtful that Mayo's incision could have changed the issue.

More successful than in the preceding two cases was the application of Mayo's incision in the following instance. The events of the case, while demonstrating that the character of the infection was not of an excessive virulence, yet illustrates the many difficulties the surgeon may have to overcome in bringing the trouble to a successful termination:

Isidor R., nine years old, admitted Aug. 27, 1899. Having been, eleven days ago, accidentally thrown off a car, his right knee was cut. Immediately afterward a practitioner had sewed up the small wound. The second day after the injury he vomited, the third day great swelling of the knee with excruciating pain, a severe chill and high fever set in, whereupon the stitches were removed. Since then a number of rigors had occurred, and the patient was sent to Mt. Sinai Hospital. We found a deeply prostrated boy, his temperature 103°F., pulse 140, with the facial expression of collapse, the entire right thigh enormously swollen and abnormally indurated. On the external aspect of the knee a granulating linear and patulous wound was seen, from which pus was oozing and through which a probe readily penetrated into the knee-joint through a rather narrow sinus. The joint was much distended by pus. Immediately the house surgeon, Dr. Allen, opened the joint by Mayo's incision. The entire capsule was found to be sloughing and most of it was excised. The cartilages looked normal. After packing the wound the limb was put up at an acute angle. The next day the fever was still very high, the thermometer indicating 105.6° F. The boy was anesthetized, and the packings being removed, it was ascertained that no retention was present in the joint itself. The swelling of the femur not having subsided, the suspicion of osteomyelitis became confirmed and was verified by the subsequent events. The cartilages became gradually separated and sloughed off, and a number of periarticular abscesses, both of the leg and of the thigh formed, and had to be opened one after the other. For each of the many changes of the dressings, the boy had to be anesthetized with chloroform. He bore the anesthetic excellently, and the manipulations could thus be done rapidly and smoothly. Portions of the epicondyles of the femur as well as parts of the head of the tibia necrosed and were gradually cast off. By Sept. 26 the febrile state had ceased, but the wound did not look well, the exuberant granulations still manifesting a tendency to ulceration and sloughing. On Oct. 24 the head of the service revised the wound under anesthesia. All the granulations were scraped away. The head of the fibula, necrosed and detached at the epiphysial line, was found floating in an abscess occupying the interosseous space. Careful search not revealing the presence of other abscesses, the rough and uneven articular surfaces of femur and tibia were shaved with a strong cartilage knife, then brought together in their normal position

the first time since admission. The retracted skin flaps were dissected up sufficiently to permit partial approximation of button sutures, and the limb was dressed in the extended posture. The next day the patient's temperature was normal and remained so to the end. In a fenestrated plaster-of-Paris splint the wound healed gradually. Bony union was present by Dec. 1, and the patient then began to walk. The ultimate healing of the wound was retarded by the lack of integument caused by its retraction, but was ultimately accomplished. The boy was discharged cured on April 8, 1900, with a firmly anchylosed joint, and no appreciable shortening.

We shall wind up this subject by bringing another history, quoted from my text-book on surgery. It contains a lesson and a warning:

Max Loffmann, butcher, aged twenty years. Admitted Oct. 25, 1885. On Oct. 12 the submuscular recess of the knee-joint was accidentally incised with a filthy butcher knife. Synovia escaped from the small puncture, and the patient walked a distance after the accident. The next day suppuration of the joint set in with a rigor, but the local practitioner—the patient lived in Jersey City—continued to dress the wound with strips of adhesive plaster. Thirteen days after the accident the patient entered Mt. Sinai Hospital. He was intensely septic, had a dry and foul tongue, high and continuous fever, and large quantities of thin, ichorous pus were seen escaping on slight pressure from the distended joint. Immediately the joint was incised in five places, when it was found that the synovial lining was coated with a greenish gray adherent and putrid membrane, similar to that seen in pharyngeal diphtheria. In making the incisions, a number of small periarthritic abscesses of the size of a pea were traversed by the knife. Continuous irrigation was installed at the same time. The fever remained unabated and locally new abscesses formed around the joint. Therefore, Nov. 4, consent to an amputation was urged upon the widowed mother of the patient, her only son, who, however, declined to permit it, suggesting that an attempt ought to be made to save the limb. Against his better judgment, on Nov. 6, the author performed excision of the knee-joint. As a matter of course, all the newly made wound surfaces were again infected, and profuse suppuration followed, the pus remaining thin and ichorous as before resection. Nov. 18 profuse arterial hemorrhage occurred from the wound. This was temporarily checked by the application of Esmarch's band. Hastily summoned to the hospital the author found the patient blanched and pulseless. A saline infusion seemed to have improved the pulse sufficiently to permit of amputation, which was quickly done in the middle of the thigh. But the patient expired before the Esmarch band was removed. The post-mortem examination revealed a sieve-like perforation of the popliteal vein, and a large oblong defect of the popliteal artery, both of which were found exposed and were surrounded by a massive blood-clot. The walls of the cavity containing the clot consisted of broken down and necrosed tissue. The sawn surfaces of the tibia and femur were necrosed, their edges jagged and eroded. There is little doubt that an early amputation might have saved the patient's life.

In concluding our subject, mention must be made of gunshot injuries to the knee-joint, the statistics of which, drawn from the records of pre-antiseptic wars, presented, whenever an attempt had been made to conserve the limb, most formidable mortality. This mortality rose sometimes to 100 per cent., and compelled the surgeons to condemn every attempt at conservation, and to amputate immediately above the knee. This was the status of knee-joint surgery at the conclusion of the Franco-Prussian war. In the Turco-Russian war, which was ended by the peace of St. Stefano, antiparasitic surgery had its first extensive trial, and came out of the ordeal triumphantly. The surgeons sent by the Baltic University of Riga to serve in the Russian army, foremost among them Bergmann, treated a long series of gunshot fractures of the knee-joint conservatively and antiseptically. No probing was allowed, the surfaces were merely cleansed, disinfected and the limb, being dressed antiseptically was put up in a plaster-of-Paris splint. Almost all of the limbs thus treated were saved. Some joints even regaining their mobility. The lesson taught by that war was verified by the experiences of all subsequent wars, notably by our Spanish and by the Transvaal wars. It demonstrated over and over again that gunshot penetrating the human body rarely carried infection with it, and that gunshot wounds of the limbs, if not associated with dangerous hemorrhage, rarely demanded active surgical interference beyond cleanliness and rest.

Whether the experience of civil life is similar to that of war, the author cannot say, having had no opportunity for personal observation.

---

## WHAT OUGHT WE TO EXPECT FROM CARDIAC DRUGS IN HEART WEAKNESS?*

BY O. T. OSBORNE, M.A., M.D.,
OF NEW HAVEN, CONN.;
PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS AT YALE.

Several causes have of late years been at work to produce all sorts and kinds of neuroses of the heart or debility of the heart muscle and to hasten that degeneration of the circulatory system that comes normally only late in life. The principal causes of this ever-increasing cardiac and arterial weakness are the high tension of our daily life, the nervous strain of some of our pastimes, as bicycling and automobiling in cities, and not the least cause is the constantly and recklessly increasing consumption of coal-tar products for pain, whether for the omnipresent headache, or for simple neuralgias. One hardly realizes this daily tension and its effect on our hearts unless

* Read at the Annual Meeting of the American Therapeutic Society, held at Washington, D. C., May 11, 12 and 13, 1903.

we analyze it. We rise on time in the morning (whether by an alarm clock, by the call of a servant, or by habit), eat breakfast and read the paper on time, a clock in every room and a watch frequently in our hand. We then, on time, meet office and outside engagements, college appointments, consultations, always and constantly carefully predeciding the amount of time that will be required and timing the next engagement by this decision. We then carefully subdivide this time and note by our watches even how long we can discuss a subject. An appointment kept by the other party even one minute late makes us restless. During the day long flights of stairs are rushed up, or elevators taken that go with a rush and stop with a plunge. If we drive, either horse or automobile, by the carelessness and haste of bicyclists or pedestrians our hearts stop, jump, or receive the vasomotor contraction check from the sudden anxiety lest we do an injury. If we are in a car or vehicle managed by some one else, we often receive the same real or needless shocks to our nervous systems and hearts. If we are ailing we fight nature's signal to relax and still keep up the pace. If we are actually sick, unless we are seriously ill, we fight and wrestle with the disease, whatever it may be, instead of calmly giving up and allowing the disease to be temporary master of ceremonies. Nature is badly hampered by nervous restlessness and the consequent impaired circulation. A calm mind and an even heart will allow nature to expel the disease if acute, and will mitigate or obstruct chronic disease until the last rampart is taken and the last gun fired.

You have only to change the subject of the above sentences to describe the lives of most men and women of our rapid age and country. Even the school children, and I might say the young children, see too much, do too much, are amused too much, receive too much, compete in school too much, are taught too much, are awake too much for the welfare of their circulation and nervous systems.

Other causes of cardiac debility are oversmoking in young men and too great a use of alcohol in young girls for the ever-increasing frequency of dysmenorrhea. Therefore hygienic treatment, hydrotherapeutic treatment, graded exercise, rest cures, and cardiac tonics are all prescribed more and more year by year.

To enumerate some of the types of cardiac weakness, we might divide them into acute and chronic debility. Acute debility could be due to any of the acute inflammations of the heart, or to acute dilatation, heart strain or athletic heart, which is a term that signifies a definite condition and I believe has come to stay; to collapse, which is really more of a paralysis and hence dilatation of the blood vessels; to syncope; to angina pectoris, and to the cardiac muscle degeneration due to fever.

Chronic cardiac weakness is due to chronic simple dilatation or to broken compensation in valvular disease, to myocarditis, to fatty degeneration of the heart muscle, and to general or local arteriosclerosis. Besides these positive disorders we have all sorts and kinds of neurotic disturbances giving both acute and chronic symptoms. It is unnecessary to even mention the symptoms and signs of any of these various cardiac upsets, but the successful treatment of any of them depends upon the proper understanding of the pathology of the case, and this pathology can only be made positive by a correct diagnosis of the condition. Many cases, however, require not only careful immediate study and discrimination, but even prolonged observation to positively decide the difference between an organic lesion and a neurotic irritation, and until the pathology of the case is understood the treatment will often be unsuccessful and perhaps absolutely wrong.

It is not my purpose to take up each condition above named and then map out a treatment, but I believe if we have some of our old well-worn tools sharpened we may the better mold the flagging heart into a normal condition. Which particular tools each of us will use depends upon our own judgment, and I might say individuality. Our tools in this case are the cardiac tonics and stimulants, and perhaps a little sharpening may make these tools the more ready for use. Let me here say that in speaking of the medicinal treatment of cardiac weakness I by no means intend to minimize or belittle the all-important general treatment above mentioned.

Drugs which increase the strength of the cardiac systole or which increase arterial tension increase the blood pressure in the aorta and consequently increase the activity of the circulation in the coronary arteries, and improve the nutrition of the heart muscle. Hence only such drugs as meet these requirements can be cardiac tonics.

If I may be pardoned a definition or two, I would describe a cardiac tonic as a drug that will more or less permanently strengthen the heart and pulse, and leave the heart in better condition after its action has ceased than it was in before. A cardiac stimulant, on the other hand, is a drug which will stimulate and perhaps for a short time strengthen a weak heart, but when its action has ceased the heart is left really in poorer condition than before unless the cause of the weakness for which it was given has ceased to act. In other words, it irritates the heart to better work, but at the expense of its reserve energy. Some drugs partake of both of these properties, being both quickly stimulant and leaving some permanent increased strength of the heart. Most cardiac tonics act slowly and cause the best results only after a more or less prolonged use. To meet the condition of shock or heart failure, or any sudden cardiac weakness, those drugs which are quickly stimulant to the heart and vasomotor system are indicated. It is a question of momentary emergency and not a question of cardiac nutrition, hence acute cardiac weakness calls for a cardiac stimulant, while chronic cardiac weakness calls for a cardiac tonic.

The principal cardiac tonic is digitalis, while the drugs which resemble digitalis in their action

are strophanthus, sparteine, cactus, convallaria, adonidine, and last, but not least, suprarenal preparations. Stimulating cardiac tonics are strychnine and caffeine, while the cardiac stimulants are alcohol, ammonia, camphor, nitrite of amyl, nitroglycerin and ether.

I do not intend to bore you by taking up many of these drugs, but will briefly state what we ought to expect therapeutically from a few of the most important, as I believe that it is difficult to always select the best drug for each case of cardiac upset, and that it is very easy to misuse a cardiac drug.

The queen and peer of all cardiac tonics is digitalis, and, though it is so well understood, a few words concerning it may not be amiss. The action of a therapeutic dose or the primary physiological action of digitalis is a slowing of the heart, an increase in arterial tension, an increased output of urine, and a diminution or disappearance of dyspnea, edema, exudates, and vasomotor, trophic and digestive disturbances due to the impaired circulation. The heart should rarely be slowed by digitalis below sixty beats per minute. If it is slowed beyond this point, or there is a feeling of constriction in the head, or there is a distinct reduction of the amount of urine passed in twenty-four hours, or the pulse becomes irregular, or there is nausea or vomiting, too much digitalis has been used and it should be stopped. Any or all of these symptoms can develop during the administration of therapeutic doses, due to the so-called cumulative action of this drug. This may be caused by some chemical condition in the gastro-intestinal canal causing rapid absorption of several doses incompletely previously absorbed, or the rate of excretion may be diminished by the kidneys not acting well and the above symptoms of overaction can develop. Hence, when giving large doses of digitalis, the patient should be seen frequently.

The conditions improved by this drug are those of chronic cardiac weakness from any cause except when due to myocarditis or to fatty degeneration, or, more definitely, digitalis should be used in broken compensation in valvular disease, in simple dilitation, in the irritable or weak heart of nicotine poisoning, in strained heart from overwork, overathletic exercise, severe marching, mountain climbing, etc.; also where there is poor vasomotor tone, and where there is edema or exudations with no serious kidney lesions.

The action of digitalis in slowing the heart by its action on the pneumogastric nerve gives the heart a much-needed rest, and the action on the cardiac muscle making the contractions more effective and more complete, thus acts as regulated calisthenic exercise, and the cardiac muscle is increased in thickness and strength. The greater force with which the blood is expelled through the aortic orifice plus the contraction of the blood-vessels so raises the blood-pressure in the aorta that the circulation through the coronary arteries is increased and the nutrition of the heart is improved. The abnormal valvular conditions without adequate compensation that digitalis would most benefit are those in which slowing of the heart would be of value and those in which hypertrophy of the left ventricle would be of value, digitalis acting with the greatest force upon the part of the heart that has the greatest amount of muscle tissue, namely, the left ventricle. As far as the lesion goes digitalis is of greatest benefit in mitral insufficiency, next in mitral stenosis, next in aortic insufficiency, and next in aortic stenosis. The greatest amount of benefit from slowing of the heart is seen in mitral stenosis, while in aortic regurgitation a prolonged disastole due to much slowing of the heart would be a disadvantage, while in aortic stenosis the strong left ventricle contracting against a great resistance should cause digitalis to be used with care. The satisfactory action of this drug when compensation is weakened in valvular disease may be many times repeated, but sooner or later in many cases of severe valvular lesion with recurring incompetency the cardiac muscle becomes so deteriorated that digitalis is no longer able to restore the hypertrophy. Some patients do well with small doses of digitalis long continued for months and even years, other patients with valvular disease and incompetency after the hypertrophy has been restored by digitalis may not again need a cardiac tonic for months until some unusual exercise or mental anxiety or severe sickness has again broken the compensation, and again digitalis will improve the condition. Often, however, in cases that have repeatedly taken digitalis, or in some patients always, one of the other cardiac tonics will serve us better than will digitalis.

In any condition in which the right side of the heart is dilated and incompetent without valvular lesions, as occurs in pulmonary disturbances such as pleurisy, empyema, advanced tuberculosis, and especially emphysema, digitalis is of benefit.

In conditions of sudden cardiac failure or shock from any cause the action of digitalis is so slow, even if given hypodermatically, that it should not be relied upon to meet the emergency. If the shock or cardiac distress can be overcome for the time being by other drugs, digitalis given at the time will in some hours begin to add its powerful stimulation to the heart and blood vessels.

In acute endocarditis occurring as a complication in acute rheumatism it is a hard question to decide as to whether digitalis should or should not be used. On the one hand the heart at this time should not be stimulated to more sturdy contraction. On the other hand the slowing of the heart by digitalis at this time can but do good by modifying the movements of an inflamed organ. If the heart with endocarditis is beating at the rate of 110 beats per minute it would seem good treatment to cause such physiological rest as would be produced by reducing the pulse rate to 80 or 90 beats per minute, or about 30,000 beats less in twenty-four hours, and this by a drug that will not weaken the heart.

In the feeble heart of myocarditis and of fatty degeneration the utility of digitalis is much less

pronounced, and the advisability of using it at all has been questioned. However, in many of these cases if the drug is given cautiously in small doses it will prove of considerable benefit, as many times we are not certain that there is actual degeneration of the cardiac muscle, and also it is impossible to decide how extensive the degeneration is even if we assume that it actually exists. It is plain that we should not deny the patient the possible benefit of digitalis, though at the same time its action should be carefully watched. If the cardiac muscle is not overstimulated at the same time the pressure in the aorta is made nearer normal the better circulation through the coronary arteries may delay the progress of the degenerative process unless there is serious atheroma.

Digitalis should not be used in endarteritis or atheroma and hence ordinarily not in aneurism.

In the insomnia of neurasthenics or where there is general vasomotor debility, when the patient is drowsy when up and wakeful when he lies down, the tone of the blood-vessels being so poor that the blood tends to gravitate to the lowest part of the body, digitalis acts often as a good soporific. It may be used for this purpose alone or if given conjointly with some hypnotic will make a much smaller dose of the latter successful than when it is used without the digitalis. In fact in neurasthenic conditions or conditions of vasomotor ataxia digitalis is a general tonic to the whole system, improving the general circulation and increasing the general nutrition.

In delirium tremens whatever cardiac treatment is given should be given hypodermatically, as drugs administered by the stomach are either not absorbed at all or are absorbed very slowly, which accounts for the harmlessness of the enormous doses of digitalis given by the mouth in this condition.

When there is edema of the lower extremities from anemia, and where there are effusions without kidney lesions, and when there is chronic liver disease, digitalis combined with other proper treatment is always of benefit.

As to the use of digitalis in renal inflammation, the writer is of the opinion that no fixed rule can be given. Theoretically, in acute renal inflammation digitalis should not be used. The same is true in uremic poisoning. However, with low vasomotor tension and a weak heart digitalis should be tried, in not too large doses. If it does not give good results in thirty-six or at least forty-eight hours, it should be stopped. If the results are good the size of the dose should be diminished, as overaction from digitalis can certainly readily take place in kidney lesions.

The contra-indications to the use of this drug are a high tension of the arteries, atheroma, a weak cardiac muscle from prolonged fevers or from fatty degeneration, myocarditis, and ordinarily a serious kidney lesion. Inflammation of the stomach or even severe dyspepsia should cause some other cardiac drug to be substituted.

The best substitute for digitalis is strophanthus, which I am accustomed to describe epigrammatically as "acting just like digitalis, only less so;" viz., it is less of a cardiac muscle-stimulant, less liable to produce nausea and vomiting, less liable to cause cumulative action, produces less contraction of the blood vessels, and, perhaps, by directly stimulating the kidney, is a little more of a diuretic.

The indications for preferring and using strophanthus in place of digitalis might be stated as: (1) When there is need of a cardiac tonic and digitalis produces nausea, vomiting, and too great an increase of the blood pressure; (2) when a cardiac tonic is indicated and the blood pressure is already high; (3) when a rapidly acting cardiac tonic is desired; (4) when there is more nervous irritability and weakening of the heart than actual muscular debility or incompetency; (5) children are very susceptible to the action of digitalis, and hence strophanthus is many times a better drug for them when a cardiac tonic is indicated.

To briefly characterize the less important cardiac tonics, we may say that a therapeutic dose of sparteine sulphate should slightly slow the heart, regulate its rhythm, prevent its nervous irritability, slightly diminish the pulse tension, and moderately increase the output of urine. This drug is not a substitute for digitalis. The indications for its use are irregularity and nervous irritability of the heart, especially when conjoined with general nervousness. I have seen it of marked advantage in the disturbed cardiac action combined with increased tension of the arterioles and diminished output of old age. Muscle or fatty degeneration of the heart, low pulse tension, and dilatation of the heart, or acute cardiac weakness should prohibit the use of this drug.

In regard to cactus, my observations, when a fresh active preparation of the fluid extract has been used, have shown that it would regulate the heart, quiet its nervous irritability, and render large doses or the constant use of strong cardiac tonics often unnecessary. This drug does not cause increased cardiac muscular strength as does digitalis. It is however, of value in having no cumulative action, in seeming not to wear itself out, and to have good action after compensation has been reestablished by digitalis in valvular disease and still some cardiac tonic must be given to keep the compensation intact. When the heart is weak in convalescence from acute disease and digitalis is not a good drug to use cactus is beneficial. The same is true in the debilitated heart of old age when digitalis is contra-indicated on account of its so markedly raising the blood-pressure. In functional disturbances of the heart, as arhythmia, palpitation, or tobacco heart, this drug is of value.

Convallaria and adonidine are to me unsatisfactory drugs.

Barium chloride, though a drug not much used, has a powerful stimulant effect on the heart muscle, and causes the blood-vessels to contract. It acts quickly, and should perhaps be resorted to more frequently than it has been.

The action of suprarenal is now so well understood that it need not be more than mentioned except to emphasize the fact that it acts as a vasomotor and cardiac stimulant only when absorbed from the nose or mouth, and not after it has been swallowed into the stomach.

Of the two stimulant cardiac tonics mentioned, viz., strychnine and caffeine, the former is so much and so well used as to only require the caution that we do not inaugurate its good work too soon in acute disease, but should rather reserve it for the coming emergency. Also, as a general bracer in debilitated conditions or in conditions requiring tonics it is used too frequently and too much. In other words, we are too liable to continue to stimulate our debilitated cases rather than to rest them, and we are just now in the strychnine age, almost every patient receiving strychnine in some form.

Now, what should we expect from caffeine in therapeutic dosage? It quickens the heart, increases the tone of the blood vessels, increases the rate of respiration, stimulates the cerebral functions, increases muscle tone and power, diminishes fatigue, increases the output of urine especially the watery element, and hence raises the specific gravity of the blood, which will then get more water where it can find it.

The indications for the use of this drug are (1) as a cardiac stimulant; (2) as a cerebral stimulant; (3) as a muscle stimulant; (4) as a diuretic; (5) as an antidote in poisoning.

As a cardiac stimulant caffeine may be used at any time when such a stimulant is indicated. It acts quickly to tide over a period of cardiac depression, but is not as quick in its action in acute collapse as the reflex stimulation of a strong alcoholic preparation or the stimulation of ammonia. It is, however, a strong adjunct to the above, and with strychnine makes an active respiratory and cardiac stimulant with no secondary depression, and leaves the heart better than it found it. If there is a good deal of nervous excitability and muscle restlessness other cardiac stimulants and tonics had better be chosen. The same is true where there is high vasomotor tension. As a cardiac stimulotonic, caffeine is indicated in prolonged fevers in place of too much alcohol, and is good in typhoid fever in the form of a cup of black coffee given once or twice in the morning. It is, of course, best to avoid it in the afternoon on account of its tendency to cause wakefulness. It is a good adjunct or temporary substitute for digitalis, but is not a permanent substitute for the latter in cardiac dilatation or in broken compensation. As a cardiac tonic in weakened heart action with poor circulation and mental sluggishness it is often effectual, but patients with good compensation in valvular disease had best avoid the stimulation from much tea or coffee.

As a cerebral stimulant perhaps no drug equals caffeine, not only in cases unused to its action, but in those accustomed to its use.

While we cannot say that there is a true coffee or tea habit, *i. e.*, an intolerable and uncontrollable desire for caffeine, still at the regular hours for coffee and tea stimulation, if it is omitted, the majority of patients miss greatly its effects. The hard brain-worker at irregular hours, as editors, reporters, authors, and students just before examinations, increase the number of hours in which the brain will work well by frequent cups of coffee, learning that it is the best and most effectual stimulation that they can take and leads to no immediate secondary depression.

As the coffee wakes up the brain, so to speak, it also stirs up the spinal cord and peripheral reflexes. The man after this cerebral stimulation then smokes a good deal, which soothes the spinal irritation, and he then, having coffee plus tobacco, can do an immense amount of brain work. If this is kept up long, sooner or later, depending upon the individual endurance, a nervous, irritable condition supervenes, with insomnia, anorexia, loss of weight, tremulous tongue, perhaps some trembling of the hands, with a pale or yellowish skin due to disturbed liver function and perhaps some kidney or bladder irritability, with probably a nicotine heart. We have then a neurasthenic to treat, which means to stop all coffee, tea, and tobacco, give mental rest, change of air and scene, and the institution of every legitimate means or subterfuge to produce sleep.

The contra-indications to the use of caffeine are palpitation, irritable heart, high blood pressure, cerebral or spinal inflammations or irritations, insomnia, neurasthenia, and acute genito-urinary inflammations.

Now, a word as to the much misused cardiac stimulant alcohol. There is a considerable difference of opinion to-day as to the value of alcohol as a cardiac stimulant. Its action on the vascular system, however, is marked and positive. The irritation which strong alcohol in any form causes on the mucous membrane of the throat, esophagus and stomach acts reflexly through the medulla to cause vasoconstriction, and hence a rise of blood-pressure, and increased blood-pressure is always a stimulant to the heart. After alcohol is absorbed into the blood, where it circulates as alcohol, it cannot, in my opinion, by its physiological action on the vasomotor centers, on the blood-vessels, and the heart, ever be a stimulant, although as its secondary effect is to dilate the blood-paths, this very fact of increasing the peripheral circulation may better the condition of the heart. Through, then, the irritant impact of the alcohol on the mucous membrane the blood-pressure is first raised, but when it is absorbed the blood-vessels dilate, especially those on the surface of the body. This relieves any spasmodic contraction of the peripheral blood-vessels, whether from fear, from pain, or from chilling of the body, and this equalization of the circulation relieves any internal congestion that may be present. By this widening of the blood paths, provided no condition of shock is present, alcohol will relieve the laboring of a weakened heart. If too large doses of alcohol are given, this vasodilatation goes on to

partial paralysis of the blood-vessels, and a weak action of the heart from this cause alone will occur. Hence in shock where the blood-vessels are widely dilated or perhaps paralyzed either from chloroform or ether narcosis, or from morphine narcosis, alcohol, except for its primary stimulant action in small doses, would do harm and is contra-indicated.

The exact action of alcohol on the heart itself is not proved beyond a reasonable doubt. Certain it is that overdoses of alcohol after absorption are depressant to the heart muscle, to the muscle fibers of the blood-vessel walls, and to the vasomotor center in the medulla. In sudden cardiac failure the reviving action of alcohol seems to me to be due entirely to the reflex stimulation of the mucous membrane of the throat and stomach. By this stimulation we cause an increased cardiac frequency and a slightly raised blood-pressure from the contraction of the arterioles due to the reflex action on the medulla. This action, which occurs before much alcohol has been absorbed, may tide over the condition of acute cardiac failure, and if not much alcohol has been given, there will be no future cardiac or vascular depression. If too much alcohol has been administered and absorbed the result will be to increase the previous depression unless more fresh alcohol is given for its continued stimulant reflex effect. If the previous doses are not too large and are hence rapidly burned or eliminated the effect will be continued stimulation and not depression. In conditions of high temperature where the heart is very rapid from the stimulation of the fever, from the irritation of the toxins in the blood and from nervous irritability, alcohol, by quieting the nervous system, dilating the peripheral blood-vessels, and possibly combating the toxins in the blood, generally reduces the temperature and slows the pulse. If the dose is properly regulated this action will be found to be continuous for good. Too large doses or too frequent administration of alcohol may do one of two things; either stimulate the brain and cause more excitation, increasing the temperature by increasing muscular irritability and restlessness, and causing enough of its local reflex irritation to make the pulse bounding and full, or, if it is too rapidly absorbed, it will give the symptoms of alcoholic depression on the circulatory system. Hence in acute cardiac failure to get the stimulant effect of alcohol it must be given concentrated, as exemplified by brandy, whisky, gin, rum and champagne, and in small doses. To keep up this stimulation, another dose must be given in from fifteen minutes to half an hour or an hour, depending upon the continuousness of the heart weakness, in order to repeat the stimulation of the irritation. As just stated, the dose should undoubtedly be small, as the future depression from the absorption would be less than it would from large doses. If the frequency of the dose is such that alcohol piles up in the system and more is given before the previous ingested amount has been burned or eliminated, to obtain stimulation it will be necessary to give larger and larger doses, first to overcome the depression caused by the previous alcohol, and to also cause the usual stimulation. As more and more alcohol is absorbed, whether from the stomach or from hypodermic injection, depression, vasomotor dilatation, cardiac weakness, and more or less paralysis of the nervous system are sure to follow. Hence to combat continuous or persistent cardiac failure or depression alcohol is the poorest stimulant we can use, and if much is given we are poisoning the system and adding depression to depression that is already there, and the treatment is vicious.

In conditions of prolonged fever where alcohol is given no more frequently for any length of time than every three hours, one dose is probably eliminated or burned before the next one is given, and we get the primary stimulation plus the dilatation of the peripheral vessels, which equalizes the circulation and reduces the temperature.

Let me parenthetically say that I have often obtained the same good circulatory results in sthenic fever from small doses of nitroglycerin that I have obtained with alcohol.

In serious feverish conditions undoubtedly the narcotic effect of alcohol in quieting the patient who is highly alert to his danger, may be of distinct advantage, as mental worry and anxiety are great disturbers of the heart and circulation, and should be overcome by any legitimate means.

## A STUDY OF GOOD RESULTS IN HIP DISEASE.*

BY V. P. GIBNEY, M.D.,
OF NEW YORK.

A MEETING of the Academy in a Summer month precludes the introduction of a scientific paper, and the few fellows who have acquired a habit of attending are entitled to a consideration which the writer feels in duty bound to extend. The selection of a title, therefore, carries with it an effort to make a practical talk on some questions that are always appearing to the body politic in medical circles.

A question that confronts the doctor in the early stage of hip disease is, Can a "good result" be obtained? An experience of more than a quarter of a century in dealing with diseases of the bones and joints ought to enable the possessor of such an experience to define "good results." The best result that any form of treatment can secure is perfect restoration of function without shortening or deformity. Such a result is so rare that the term "good" has been accepted as satisfactory. Why the "best" is so rare it may be well to set clearly before this audience the meaning of "hip disease." A technical definition is not attempted, for this will not give one a clear idea of the malady under discussion. Practitioners are too prone to rely on certain stereotyped signs for a diagnosis. For example, if one finds on examination of a child in whom hip disease is suspected a limp more or

* Read before the New York Academy of Medicine, June 4, 1903.

less pronounced, a loss of contour in the nates of the affected side, an inability to flex, to extend, to abduct, and to adduct to the normal limit without pain or resistance, the conclusion is often reached without analyzing the finer points in the clinical and personal histories of the case. Now, should all the aforesaid signs be present, a certain consideration should be given to the pathology, the etiology, and, above all, to the first appearance with the date of symptoms. There are so many lesions, quite simple in character, that impair the functions of the hip, sometimes to the point of immobilization, that mere signs of themselves cannot be accepted as absolutely diagnostic.

The hip disease under discussion this evening is, pathologically speaking, a tuberculous osteitis of the neck, or head, or the acetabulum, one or all. The lesion has its starting point in one or more of the centers of development, and long before the wonderful discovery of Roentgen careful diagnostication was reasonably accurate in locating these initial lesions. The X-ray is shedding light on these lesions and promises great assistance in the recognition of these inflammatory foci. However good a radiograph may be, it is requisite that a certain facility in interpretation is to be attained before one can say definitely whether a lesion exists or not. It may be taken for granted, therefore, that the radiograph is, up to the present time, only an aid in diagnosis.

From an etiological standpoint it must be remembered that diseases are not inherited, but that the predisposition and vital resistance are inherited. So that if an ancestor, near or remote, has had hip disease, it does not follow, by any means, that the patient in question has hip disease. Our consideration only must be accorded the vital resistance.

The clinical history is a very important factor in estimating a diagnosis. There may be at the outset an acute exacerbation, yet this is the exception. A slight limp is the first sign observed, pain in the knee only occasional, complaint when an extra function is called into play, such as pulling on the shoe and stocking and going up or down stairs, a stiffness in the morning gradually wearing off toward midday, more pain in sleep if the patient has been specially active during the day, screaming pains at night and usually without waking, a general disinclination to use the limb, and above all, the persistence of the limp. Now, all the foregoing symptoms usually precede the exacerbation that calls for medical or surgical advice some two or three months. The parents are satisfied when a neighbor suggests growing pains, or rheumatism, or malaria. Given now such a history, the test of function ought to enable one to make a diagnosis of the hip disease, the result of which we are now considering.

In the interest of the patient and the father and the mother, it must be urged, "Make a careful test of all the functions." Do not be satisfied with anything short of an examination of the patient nude and on a table or floor, without a mattress. Remember, too, that a test of the functions of the sound hip are necessary as preliminary. Comparisons can then be made satisfactorily and the meaning of hip disease now clearly understood.

Pardon, please, the mere mention of a few of the lesions that are often called hip disease, and no attempt will be made to enter into a differential diagnosis. There comes to mind at this moment a contusion of the hip, clearly traumatic, a periarthritis, either phlegmonous or rheumatic or traumatic, involving the muscular tissue or the capsule and ligaments, a coxa vara, rachitic or traumatic, a congential dislocation of the hip—easy of recognition if one will spend a little time on the case, a trauma involving the femoral neck or the periosteum of the shaft near the trochanter-major, a psoas abscess, a perityphlitis, a poliomyelitis, a neurosis dependent on an irritable spine or a toxemia or a hysterical hip.

In this prolonged definition with examples it may be claimed that "good results" are being crowded to the rear. The writer never has any apology to offer for time occupied in emphasizing points in early diagnosis and pathology. He regrets to say that the knowledge displayed by the average practitioner on these two topics is as yet lamentably deficient.

A good result as understood by the parent is a life saved, often a limb, yet an ease in getting about unassisted by splint, crutch or cane. Over an inch shortening is not regarded with complaisance. An inch or less is satisfactory. It usually depends on the point of view and the coaching of the surgeon in charge. Comparisons are not odious, for always a deformity that might have been more hideous, a disability that might have been more disabling can be pointed out, and the situation is accepted.

A good result from the practitioner's standpoint is arrest or termination of the disease, regardless of the position in which the limb is left. Anchylosis is rather courted, and if a stable, firm union is secured, it is believed that the patient will be free from any late exacerbations and locomotion will not be seriously impaired. The claim is often made, too, that a cure with a flexion deformity enables one to sit more comfortably and to dress oneself with more ease than if the anchylosis existed without deformity. Here again the point of view is to be considered. For one whose vocation is to be a sedentary one there is no question but that an angle, say, of from 135 to 150 degrees fixation is better, but where one's vocation takes him out of doors and does not interfere with all kinds of sport, the position should be straight, that is, anchylosis, if anchylosis must exist, with either flexion or adduction deformity.

Studying further this result, which may be called the medical result, one finds the patient as puberty approaches sometimes dissatisfied with the existing deformity, and relief is sought at the hands of the general surgeon. An osteotomy, either simple or cuneiform, is done and the limb is placed in what is honestly believed to be a good position, that is, straight with the axis of the body. It matters little what means are em-

ployed for fixation, disappointment comes on removing the appliance, for the deformity has not been fully corrected. It is within the observation of the writer to have seen many, many instances of such failure. And here again comes the philosophical assurance that this is much the best result one could expect. All the time one finds apologies for results in hip disease, and the profession has not awakened fully to the belief that better results can be obtained than statistics already furnish.

What does the orthopedic surgeon regard as a good result? Here again we lack unanimity. One whom the lay press has placed at the pinnacle has claimed that anchylosis without deformity is the best we can expect. Plaster-of-Paris is used to allay irritation and encourage anchylosis. The writer of this paper has seen a few results from prolonged use of plaster-of-Paris supplemented by axillary crutches, but he has not seen many results after the prolonged use of plaster-of-Paris as a fixation dressing associated with the use of the limb. It is his impression that statistics of results in this country would be hard to obtain.

Surgeons who claim that early excision yields good results are not able to furnish the proof. If the disease on section is found extensive, too much of the bony tissue must be sacrificed, and not infrequently a flail joint is the result. Early excision is not popular in this country because of the mortality and of unstable limbs.

Among orthopedic surgeons whose practice is not confined to splints, there is a growing tendency to remove by small aseptic operations the foci of disease demonstrated by the radiograph. Some find it advantageous to evacuate small collections of pus by means of the scalpel when the needle will not suffice. All of these operations, however, should be followed by protection apparatus. It has been abundantly proven that the best results are obtained by the early use of splints that immobilize the joint. Such appliances, to be efficient, must be long continued, irrespective of that bugbear of the laity and some practitioners, muscular atrophy. Among the best informed of orthopedic surgeons the results attained over a quarter of a century ago by the late Charles Fayette Taylor have not been surpassed, and this pioneer claimed that muscular atrophy was a thing to be courted.

The good results which are acceptable to men in our branch of surgery are results with the minimum amount of shortening, without deformity, and with the maximum range of motion. Our aim however, is to get not "good results," but "best results," and the more we can approach perfect function the better we are satisfied. Results after all must be studied on a basis of the stage in which well-recognized methods of treatment are begun. The keen diagnostician will recognize the lesion before the deformity arises and at an early stage, while the poor diagnostician will fail to recognize hip disease until the mother of the child has already made the diagnosis herself. Then the second stage, that of deformity, will have been reached and the advantages of early protection are lost. The tardy recognition of the value of instruction in orthopedic surgery by the medical schools throughout the country is largely responsible for the destruction of hip joints and the hopelessness of restoring functions to points thus impaired. And yet we have reason to hope for better results because nearly all the large and well-equipped schools of medicine have within the last decade established such chairs, and the younger practitioners who will ere long make their influence felt will thus increase the number of those who get efficient treatment before the second and third stages are reached.

The results ought to be good and many cures ought to be obtained, cures that have no trace of deformity or impairment of function. Where treatment is delayed until the bacilli have already played sad havoc with the head and neck of the femur, fair results may be obtained by close attention to details and by intelligent home cooperation. Here one must be posted on the damage to tissue an abscess can cause, and steps will naturally be taken to curb its virility. Occasionally a fine result can be secured, but this can hardly be expected.

In the third stage we must be content with correcting deformity and eradicating necrotic areas and sinuses. Results that will satisfy can be secured if we maintain the best position of the limb. If by faulty technic we fail to hold what we get, then do not hesitate to repeat efforts at correction, not resting satisfied until the maximum benefit has been secured as a lasting result.

---

## CHRONIC NEPHRITIS WITHOUT ALBUMINURIA.

BY ARTHUR R. ELLIOTT, M.D.,
OF CHICAGO;
PROFESSOR OF MEDICINE, POST-GRADUATE MEDICAL SCHOOL.

The writings of Rayer, Dieulafoy, Lancereaux, Lepine, Stewart, Wilks, Mahomed, Purdy, Saunby, and other authorities have made us familiar with the fact that albuminuria may be temporarily or mainly absent from the urine during nephritis, especially during chronic interstitial nephritis. While this fact is now common knowledge it is not so fully appreciated that nephritis may progress to an immediately dangerous stage, with continued absence of albumin from the urine. It is worth noticing, especially, that often, notwithstanding that the urine is absolutely free from albumin, cardiovascular developments may be far advanced and the fatal issue not far distant. Even symptoms, ordinarily included among the terminal developments of chronic nephritis, may prevail without the urine giving the albuminous reaction. Thus albuminuric retinitis, chronic uremia, or cardiac incompensation may become established and presage an early termination of the case without the presence of albuminuria.

The absence of albumin is not confined to chronic interstitial nephritis, but has occasionally,

although more rarely, been noted in chronic parenchymatous nephritis and acute nephritis, even of the postscarlatinal type.

I have chosen from a series of cases that have fallen within my experience the following examples, which I shall briefly relate, as illustrating how extreme may be the development of chronic nephritis, without the occurrence of albuminuria, appreciable by the methods in use. In testing for albumin, I have, in every analysis, used several tests, in order that my results might be devoid of the error, so easily possible when but one method is employed. I have eschewed the use of the extremely delicate tests, such as the potassiomercuric iodide, picric acid and trichloracetic acid, having long since grown to distrust them as being oversensitive and liable to error, with peptone-albumose, nucleo-albumin and alkaloids. The method pursued consists in the successive application of the potassium-ferrocyanide, Heller's nitric-acid, and the heat-with-acetic-acid tests.

*Case I.*—Young man, thirty years of age, of excellent habits and unimpeachable heredity was referred to me by Dr. L. E. Schwarz, of this city. Patient's previous history had been uneventful, save for a severe attack of the grip, lasting one month, at the age of twenty. Several less severe influenzal attacks have occurred since that date. Visual disturbances had led him to consult Dr. Schwarz, who, upon examination, found a typical neuroretinitis of albuminuric type of the left eye. There was a slight blurring of vision of upper and lower temporal fields, but central vision was never disturbed. The papilla was swollen, opaque and reddish, with all outlines lost; infiltration, opacity and swelling of retina marked. Hemorrhages were present, but neither numerous nor large, and were situated in the upper and lower nasal and temporal portions of fundus, and within three diameters of the disk. The large arterial elements were entirely obscured at points, numerous white plaques or foci of degeneration showed in the macular region, especially downward and inward, but were without regular arrangement. I am indebted to Dr. Schwarz for these details of the retinal condition. The patient displayed an entire absence of symptoms of ill health, except some dyspnea and slight precordial uneasiness upon exertion. He was habitually constipated. The prostate was found moderately enlarged, although not tender.

Physical examination revealed distinct but moderate cardiac hypertrophy, marked arterial fibrosis and tension, and the urine was entirely free from morbid characteristics, except for the presence of hyaline casts and reduction of urinary solids, below the normal average. Under treatment the retinal condition improved and the urea excretion increased, from a daily average total of 350 grains to 450 grains. In June, 1902, it is interesting to note, patient suffered an attack of primary labyrinthine vertigo (Menier's disease), no doubt due to hemorrhage into the semicircular canals of the right ear. Hearing on that side still remains markedly deficient. Not a single one of the 18 twenty-four-hour specimens of urine examined, during the twenty-eight months of my observation of this case, revealed the slightest trace of albumin. Hyaline casts in very sparse numbers have invariably been disclosed by careful microscopic examination.

*Case II.*—Woman, fifty-two years of age, of neuropathic heredity, never robust and the subject of periodic hemicrania. The clinical history of this patient's nephritis was ushered in by uremic convulsions, suddenly developing, after a few day's indisposition, from functional digestive disturbance accompanied by dizziness and headache. It was only with the greatest difficulty that patient was rescued from the severe toxemia. She lived for three and a half years, at the end of which period a second, and this time fatal, uremic development terminated the case. During this interval many single and twenty-four-hour specimens were examined, but at no time was albumin found in the urine. Casts hyaline in character were constantly to be found in the urinary sediment, although in very small numbers. Cardiovascular changes were well developed and troublesome nocturnal polyuria greatly disturbed the patient's rest. The urine frequently reached as high as 100 ounces in the twenty-four hours and was of uniform low specific gravity. The total urea and other urinary solids were greatly reduced, and it was only by the most careful supervision of the patient's habits and persistent stimulation of the emunctories that uremia was for so long averted.

*Case III.*—Woman, fifty-eight years of age, weighing 110 pounds (normal weight), first consulted the writer in May, 1901, complaining of dizziness, frequent blurring of sight, slight edema of feet and frequent nocturnal urination. No dyspnea or palpitation present. Physical examination revealed a hypertrophied heart, well developed vascular sclerosis and distinct arterial tension, which was readily appreciated by the examining finger and beautifully expressed in the sphygmogram. Heart sounds were clear and booming with marked accentuation of the second aortic. Three months after first consultation, cardiac dilatation supervened, and ever since that time a distinct blowing mitral systolic murmur has been audible, slight dependent edema has been constantly present and dyspnea of effort has prevailed. Retinal changes, present in their incipiency, progressed at the time of the cardiac incompetency, and a typical bilateral albuminuric retinitis became established with almost entire loss of vision. During the eighteen months which have elapsed since the time of these developments the patient has been under constant observation. The visual acuity has fluctuated with the general systemic condition and the circulatory integrity has been fairly maintained by the measures employed. Uremic manifestations have developed from time to time, and the patient is at present under daily attention for a serious uremic state. The interesting feature of this case is the urinary condition. In all 55 twenty-four-hour collections

of urine have been submitted to careful testing. In only three of these specimens was albumin found in demonstrable amount and this albuminuria was minimal and coincided with circulatory disturbances. The specific gravity and urea have invariably ranged low, the latter seldom rising above 200 grains in the twenty-four hours. Casts of hyaline and light granular character, but in small numbers, were constantly revealed by microscopical examination.

Latency of symptoms is a characteristic which so frequently marks the form of nephritis, known as primary chronic nephritis or interstitial nephritis, that it may almost be designated its most distinguishing feature. This lack of emphasis holds more particularly with reference to the urinary signs, but is also, although to a less extent, remarked in the general physical manifestations, particularly their subjective expression, and it prevails more or less throughout the entire course of the disease. The cases reported certainly demonstrate that latency of symptoms is not a point of absolute distinction between the early and the advanced stages, or between the slight and the severe forms of the malady. Seldom in any given case will one have at hand an unbroken association of symptoms, urinary and physical, from which to construct the diagnosis. The discrepancy between the clinical symptoms and the renal damage is often extreme and at autopsy it may seem impossible to connect the atrophied degenerated kidneys with the urine, which has been the outward expression of the disease during life. It is by no means uncommon for lesions to exist in a relatively advanced state without the patient consciously suffering from any marked disturbance of health. So much is this the rule that many, if not the majority, of these cases are revealed accidentally in persons undergoing medical examination for reasons other than the relief of symptoms, produced by the disorder, and this, even at a time when the organic degeneration has progressed to such a point as to preclude the possibility of a long survival. As a rule the diagnosis must be made during the early stages, from physical signs, rather than from subjective symptoms. When symptoms arise the disease has already existed for a considerable period, and the renal lesion is far advanced. Such symptoms as exist during the early progress of the disease represent such a slight departure from the normal that they are rarely made the subject for complaint by the patient, and may only be elicited after direct and pointed interrogation. They most commonly consist of some degree of polyuria and evidences of circulatory disturbance under strain. Polyuria is the most constant and, in the majority of cases, the only urinary symptom remarked during this period. It does not become established until cardiac hypertrophy has taken place and ever after and until compensation fails, and the blood-pressure in this way becomes lowered, it remains a constant feature of the clinical picture. In those rare cases in which, for any reason, cardiac compensation fails to become established, polyuria will be absent. Rarely is this symptom made the subject for complaint upon the part of the patient, who generally regards it as a favorable sign that urine is passed freely. The distinctive feature of the polyuria of this form of nephritis is its nocturnal character. Almost invariably the amount of night urine greatly exceeds the amount of the day's output. In well-developed cases I have seen the night urine amount to four times that passed during the day. The patient's rest is disturbed by the necessity for urination, which this excess imposes, and he consequently may rise a number of times to void urine. Various explanations have been advanced to account for this curious phenomenon, but I believe the true one to be the increase in vascular pressure, following recumbency. We often see this increased pressure manifested in other interesting ways in this disease. To illustrate, I cannot do better than to relate the following case:

*Case IV.*—Large, fleshy woman, fifty-two years of age, was operated for uterine fibroid in 1894, at which time a diagnosis of Bright's disease was made. Writer was consulted in February, 1901. Subjective symptoms were entirely nocturnal and of such a character as to make patient dread the approach of bedtime. Lying down was the signal for great mental restlessness, which frequently, for hours, precluded the possibility of sleep. Occipital headache and vertigo often came on shortly after retiring for the night, and backache of purely nocturnal development was often very troublesome. An additional source of disturbance was the necessity for urinating two or three times each night. As the result of these combined deterrents only three or four hours' sleep could be obtained each night.

Physical examination revealed a forcible cardiac apex, six inches to the left of the midsternum. The apical region was tender to palpation. Frank arterial tension and sclerosis were present. Not to go farther into the details of this case, I will merely add that its progress has been typical and eventful, cardiac dilatation having supervened this winter. The urine has been carefully observed in a routine way. Casts have been a constant feature of the urinary sediment in every specimen examined. In all 13 samples, each of them a twenty-four-hour collection, have been analyzed. Only two of these specimens gave any reaction for albumin and then a trace only. This minimal albuminuria occurred during the circulatory crisis of the past winter.

Almost invariably the normal healthy adult experiences no need for emptying the bladder during the average hours of sleep, unless he has indulged in some unusual excess of fluids immediately before retiring. The exceptions to this rule are, I believe, rare. Certain affections of the lower urinary tract, the urethra, bladder, prostate, occasionally through irritation or abridgement of the containing power of the bladder, will cause nocturnal urination. Certain systemic causes, such as nervous hydruria, diabetes, excessive acidity of the urine, pyelitis, calculous disease, etc., also

bring about this result. Excluding these causes, which result in a more or less sudden onset of this symptom and are temporary in their action, the great majority of instances in which this habit becomes established, are cases of chronic nephritis. It is necessary, before according weight to this symptom, to establish the fact that it has not always been the habit of the patient, for in rare instances such may be the case. As a rule the onset of the symptom is gradual and by such easy stages that it insensibly grows into a habit, without awakening any concern in the patient's mind.

Among the earliest manifestations of chronic interstitial nephritis are certain symptoms arising from the cardiovascular changes which are so constantly associated with this disease. The changes comprise widespread arteriocapillary fibrosis and cardiac hypertrophy. They develop *pari passu* with the renal change and go back as far as we may, so soon as the disease is demonstrable, the pulse tension is high and the artery thickened. The accessibility of the circulatory system to direct examination enables one to consult the heart and arteries for diagnostic data at a time when the urinary condition is so obscure as to leave us in great doubt. The changes in the arteries are widespread, and generally quite early in the disease become appreciable to the senses, in the well-known, stiff, tense vessel and hypertrophied heart of arteriosclerosis. As a general rule, there are only two forms of widespread arterial change recognized, viz., atheroma and that connected with chronic nephritis. Care must be taken, however, to exclude alcohol and syphilis, since both are capable of producing arteriosclerosis and myocardial changes. When this condition is met with in the prime of life, it should direct attention to the kidneys. Certain subjective manifestations soon result from this altered vascular state. The earliest symptom produced is a slight dyspnea of effort. Associated with cough, as it frequently is, the patient may suspect asthma, and seek advice for relief of the respiratory distress. Auscultation of the lungs under these circumstances will reveal nothing, and the contrast between the negative pulmonary findings and the dyspnea is suggestive. Palpitation and a sense of precordial fulness are frequently complained of. Certain obscure sensory disturbances of vasomotor origin may be the only indications present, as in the following case:

*Case V.*—Blacksmith, age thirty-four years and of 182 pounds weight. Patient temperate, but with history of past excesses. Syphilis denied and no stigmata present. Patient complains of sense of coldness of lower extremities from the knees down (cryesthesia). On close questioning confesses to recent slight dyspnea and precordial distress upon severe exertion. Reflexes normal, no disturbance of special sense impressions, sexual power unaltered, locomotion good. Physical examination reveals distinct arteriosclerosis and the cardiac apex diffuse and forcible in the fifth interspace, 5 inches from midsternum. Aortic second sound much accentuated, prostate somewhat fibrous, enlarged and tender, urine contains trace of albumin and numerous hyaline casts.

The urinary changes in the early stages of chronic interstitial nephritis are, as we have seen, inconstant and unreliable, as a means of estimating the extent of the renal dystrophy. Associated with the polyuria, already referred to, a lowered specific gravity is usually met with. The diminished density is no doubt largely due to dilution of the urine, brought about by the polyuria, but must not be entirely attributed to that cause. There is an actual deficiency of urinary solids, owing to renal inadequacy. If from any cause, such as fever, excessive sweating, diarrhea, the urine becomes reduced in amount, there is not that proportionate increase in the specific gravity which is characteristic of normal urine. Careful estimation of the urea in the twenty-four-hour urine, by means of a reliable method, will almost invariably reveal some reduction below the normal average.

Albuminuria, the classic sign of nephritis of whatsoever character, cannot be relied upon as an indication in chronic interstitial nephritis. It has been a debated question whether albumin was not sometimes totally absent throughout the disease. There can be no doubt that it may frequently be altogether absent during the early stages, that in other cases it may be absent for long periods of time or until the disease enters the final stage, and that in certain other cases the stage of the disease seems to have little influence in causing albuminuria, the urine apparently remaining free from that body so long as no intercurrent disturbance, apart from the disease, arises to cause it to appear. As the expression of a personal opinion, I would say that in many cases where albumin is apparently absent, it is really actually present, though in minimal amounts only, and these obliterated so far as chemical demonstration by the methods in vogue is concerned, by the dilution of the urine through polyuria.

In such cases its occasional transitory appearance in traces coincides with temporary concentration of urine from physiological or pathological causes. I would further express the conviction that rarely albumin may be absent during the entire course of the disease, in cases of purely cirrhotic type, and only appear in obedience to grave changes in blood pressure, brought about by circulatory causes, or as the result of some intercurrent trouble, apart from the original morbid process.

The albuminuria of chronic interstitial nephritis, even when present, is very irregular, depending upon various physiological factors, such as exercise, character of food, etc., and often at certain times of the day the urine may be free from albumin, although containing it at other times. One is not justified, therefore, in pronouncing albumin to be absent unless a number of samples, taken at different times of the day, have been examined, or better still, a twenty-four-hour collection, submitted to testing.

Without going into the matter further, it may be claimed that the presence of albumin in the

urine in this disease is uncertain, and that it consequently is but a very unreliable diagnostic guide. When present, associated with physical signs and other urinary indications, it serves to complete the diagnosis, but if absent, no contrary inference is justifiable, and the diagnosis must be constructed without its aid. Much more reliable evidence of renal change is the lowered excretion of urea, which may exist months or years before the appearance of albumin, and especially important is the presence of tube casts in the urinary sediment. Casts are undoubtedly present with greater constancy in contracted kidney than is albumin, and in the diagnosis of this disease it may be stated that the morphological evidence afforded by the presence or absence of casts may be accorded more weight than the existence or non-existence of albumin in the urine. While in the main they are associated bodies, casts may be frequently met with when no albumin exists. Albumin without casts is more rare. It is perhaps not too extreme a view to say that chronic interstitial nephritis never exists as a clinically recognizable condition without the presence of casts in the urine. They are most frequently hyaline in character, and, as a rule, exist in small numbers, so much so as to be often difficult of discovery. Patient search for these bodies will, however, always reveal them. Their number bears no relation to the severity of the renal lesion; a desperate organic condition may coincide with casts so infrequent as to be with difficulty found, as in Case II here reported. I do not wish to be interpreted as asserting my belief in the pathognomonic value of casts in the diagnosis of this disease. Although helpful to it, renal diagnosis cannot be founded on casts alone. They do not necessarily mean nephritis, being frequently the product of irritation of the kidneys, by toxic or other causes. I believe, nevertheless, that casts are invariably present when true organic lesions of the kidneys exist. The more purely interstitial the process, the less the tubes are involved in the chronic inflammatory changes the fewer will be the casts. The observations of Defendorf (*Yale Medical Journal*, December, 1902) are of interest, and I may be permitted a reference to them in view of the present tendency to regard hyaline casts as irritation products, not necessarily possessing pathological value, except in the presence of other urinary abnormalities. Especially have they come to be viewed with indifference in individuals beyond middle life, because of their frequency of occurrence. A series of 48 autopsies of cases in which urine examinations had been made some time previous to death showed that purely hyaline casts were present in 41 and chronic nephritis in 47 of the cases, permitting the inference that hyaline casts in these instances were distinctly an indication of organic change in the kidneys.

We have seen that the evidence of chronic interstitial nephritis during the early stage is of two kinds, symptomatic and physical, of which the former is uncertain and not greatly to be relied upon. The physical signs fall naturally into two classes, cardiovascular and renal (urinary). Of the latter, the most important in the general estimation of the profession is albuminuria. This symptom, in many cases, is repeatedly absent in all stages of the malady. Upon what, then, are we to rely for the diagnosis in these doubtful cases? Fortunately we have good recourse, which will undoubtedly suffice in most cases for a satisfactory conclusion. The evidence of cardiovascular changes, arterial tension and enlarged heart, with hyaline casts in the urine and a deficiency of organic urinary excretives, combine to form a symptomatic association which will suffice for a positive diagnosis.

### CONCLUSIONS.

1. Latency of symptoms is so constant a characteristic of chronic interstitial nephritis as to almost constitute its most salient feature. This obscurity involves all manifestations (symptomatic, physical and urinary) and prevails throughout the entire course of the disease.

2. Latency of symptoms does not constitute a point of absolute distinction between the early and the advanced stages or between the mild and severe forms of the malady.

3. Symptoms are especially liable to be absent and urinary signs uncertain during the early stages of chronic interstitial nephritis, consequently the diagnosis during this period must generally be made from physical signs rather than from symptoms or urinary signs.

4. Albumin is absent from the urine of this form of nephritis with great frequency. It may frequently be absent during the early stages. It may occasionally be absent until the disease enters the final stages. It may rarely remain absent from the urine throughout the entire course of the disease, the urine remaining free from albumin so long as no intercurrent disturbance apart from the nephritis arises to cause it to appear. Albuminuria, therefore, constitutes a very unreliable diagnostic sign in this disease. When present, associated with physical signs and other urinary indications, it serves to complete the diagnosis, but if absent no contrary inference is justifiable, and the diagnosis must be considered without its aid.

5. More reliable evidence of renal change is diminution in the gross amount of urinary solids, and especially significant is the presence of casts.

6. Chronic interstitial nephritis never exists as a clinically recognizable condition without the presence of casts in the urine. Although renal diagnosis cannot be founded on casts alone, they constitute a corroborative sign of high clinical value, when associated with other indications.

7. The secondary circulatory changes following chronic interstitial nephritis are so constant and characteristic as to furnish, in most cases, sufficient ground for the recognition of the disease before reference is made to the urine. The inconstancy of the urinary symptoms places them in much the same diagnostic category in chronic in-

terstitial nephritis as that occupied by the murmur in valvular diseases of the heart. The diagnosis should be made, if possible, from the physical signs and symptoms, the urinary indications being regarded as corroborative rather than as essential evidence.

## MEDICAL PROGRESS.

### MEDICINE.

**Roentgen Rays in the Early Diagnosis of Pulmonary Tuberculosis.**—The aid which this measure may furnish in diagnosing the early stages of this disease is made the subject of a paper by W. H. B. Brook and A. S. Green (English Quart. Med. Jour., Aug., 1903). They examined a large number of cases and in no single case where the physical signs pointed to disease have the rays failed to detect mischief. In some cases where the signs have been absent the rays have shown deposits in the lungs, and here physical signs have been subsequently detected. It is also shown that the extent of the disease is in some cases greater than the physician thinks. The progress and results of treatment can be watched with accuracy. The only fallacies may be caused by chalky deposits in the lungs, old healed cavities and thickened pleura, but here the history and the symptoms will help in forming a correct opinion.

**Diagnosis of Renal Tuberculosis.**—The wisdom of basing a diagnosis of renal tuberculosis upon the appearance in the urine of tubercle bacilli is questioned by P. Bazy (Trib. Méd., Aug. 8, 1903); as cases have been seen in which acid-resistant bacilli presenting all of the morphological and chromatic characteristics of Koch's bacilli have been found in the excreta of non-tuberculous subjects. Such a case came under his observation; a nephrectomy for tuberculosis of the kidney having been urgently advised by the attending surgeon. Though examination of the centrifugated urine revealed micro-organisms having the same appearance, staining qualities and resistance to decolorization by acids as tubercle bacilli, their injection into guinea-pigs failed to produce symptoms of tuberculosis; neither did autopsy, performed three months after the injection, reveal tuberculous lesions of any kind. Hence the author holds it to be the part of wisdom and prudence to prove the diagnosis of renal tuberculosis by such experimental injections, in cases in which these bacilli are found in the urine, before resorting to so radical a measure as nephrectomy.

**Specific Gravity of the Blood and Hemoglobin Estimate in Yellow Fever.**—Through a somewhat extended study of the condition of the blood in yellow fever, A. D. Albertini (Rev. de Med. Trop., Vol. IV, No. 7) has found that though the hemoglobin is increased in this condition, the specific gravity varies without any relation to the amount of the former. In illustration of this characteristic he cites a case in which upon the second day the hemoglobin was 92 per cent. while the specific gravity was 1.055; and on the fifth day the specific gravity fell to 1.045, the hemoglobin remaining unchanged. In striking contrast to this condition is the parallelism between hemoglobin and specific gravity in malaria, as demonstrated by Plehn. This investigator also found that while the hemoglobin and specific gravity curve rise and fall together in malaria, in typhoid and dysentery hemoglobin does not change from the normal though the specific gravity is reduced. Albertini believes that a study of the blood's hemoglobin and specific gravity will lend valuable aid to the differentiation of yellow fever and other infectious diseases.

**Leucocytosis Following Endovenous Injection of Bichloride.**—In 15 individuals subjected to endovenous injections of corrosive sublimate, G. Memmi (Gazz. Osped., Aug. 9, 1903) found there was an increase in the number of the leucocytes; in some of these cases the increase reaching from 2,000 to 5,000. This increase was to be seen, as a rule, from an hour and a half to two hours after the injection; reaching its maximum in four to six hours and diminishing from that time till the normal count was regained; this condition being usually reached within eighteen to twenty-four hours. The author believes that the beneficent influence of endovenous injection of bichloride is due to the increased defensive power of the organism, brought about by the leucocytosis it induces; rather than through its antiseptic influence.

**Chylous and Chyliform Exudates.**—After enumerating the varieties of milky exudates and reviewing the literature dealing with their pathogenesis, etc., A. Cipollina (Gazz. Osped., Aug. 2, 1903) gives the case-history of a patient who some years after an attack of pleurisy came under treatment for what appeared to be influenza. In the course of examination a point was reached in the chest which gave the physical signs of fluid, presumably in the pleuritic cavity. Exploratory puncture revealed the existence of a milky exudate of the variety known as chyliform adipose, which, the author believes, had its origin in encapsulation of the effusion which had occurred some years previously; this effusion having subsequently undergone fatty and granular degeneration. Clinical experience, says the author, shows that milky exudates may be met with at any age and in a great variety of conditions; they, however, show a predilection for patients afflicted with malignant tumors and serious tuberculous lesions. Their symptomatology is that of all exudates, save that in chylous ascites there may be signs of peritoneal inflammation. Chylous ascites is very abundant and the fluid reaccumulates rapidly and repeatedly after puncture. The prognosis in this form of ascites is always grave.

**Course of Diabetic Coma.**—Coma, as the fatal issue of diabetes presents itself, is one of the most important symptoms of the disease, and has been observed as a terminal symptom frequently in severe cases of the affection in young persons. V. T. Orlovsky (Roussky Vratch, No. 30, 1903) observed 3 cases of diabetic coma, and finds that notwithstanding the introduction into the organism of considerable quantities of fluids hypodermatically and through clysmata, the amount of urine may become considerably diminished, while its specific gravity is but little lowered; the amount of sugar in the urine is at times increased, at other times diminished; though the daily total may at times diminish very considerably. Typical diabetic coma accompanied by air "hunger" may develop even in those patients in whose urine there had been no dextrose for some time, nor during the attack of coma; the latter was, however, observed in but one single case, in whom the disappearance of sugar in the urine for seven days previous to the attack the author ascribes to the extreme anemia which is usually accompanied in severe cases by a diminution in the amount of sugar in the urine, and sometimes by its entire disappearance, due evidently to disturbances of the alimentary functions, and smaller quantity of food ingested. The real nature of the coma as it presented itself, could only be defined from the observation of the course of the disease in the hospital, for the character of the urine during the attack furnished no positive indication of the presence of diabetes mellitus. Contrary to Naunyn,

the author observed a considerably slower and deeper respiration.

**Diagnosis of Liver Abscess.**—Until not so very long ago, the diagnosis of liver abscess was difficult and surgeons often waited until the abscess was very large or matastases had formed in the liver, before operating. D. Schlayer (Münch. med. Woch., Aug. 11, 1903) points out the importance of counting the white cells, by the absence of a leucocytosis he could rule out a number of cases of typhoid, malaria and nephropyelitis which closely simulated hepatic abscess. It is not proper to depend solely upon the number of leucocytes in deciding when to operate and the temperature and local symptoms must also be taken into account. After an abscess has been opened, all the symptoms generally disappear, so that the diagnosis of a second abscess may be impossible. Here again a leucocyte count proves invaluable. The white cells generally sink very slowly; if they remain high for several days and complications can be ruled out, it is probable that there is another focus in the liver. The temperature curve is less reliable, since even with complete evacuation of pus there may be quite a post-operative rise. Larger abscesses, requiring further operation will generally show more than 20.000 leucocytes; the smaller ones with 15.000 to 20.000 cells will often be absorbed spontaneously or become latent. An exacerbation of a dysentery or peritonitic processes may also be the cause of leucocytosis.

**Fallacies of the Widal Reaction.**—It is well-known that a small amount of bile in the blood will give a positive agglutination, even in patients not suffering from typhoid. F. Köhler (Münch. med. Woch., Aug. 11, 1903) could even bring about an artificial agglutination by ligating the common bile duct and by injecting taurocholic acid into the blood. There is no doubt that normal serum, and more often the serum of patients suffering from blood-diseases or from disturbances of the liver with jaundice, will cause clumping of typhoid bacilli in relatively high dilution. Human bile, even when heated for two hours at 60° C., and taurocholic acid, when added directly to a culture, will also agglutinate this but the phenomenon is by no means constant. A number of chemical substances such as salicylic acid, safranin, fuchsin, etc., will behave in the same way. A positive Widal is, therefore, not pathognomonic for typhoid: it may also be due to (1) disease of the liver with biliary stasis and bile in the blood; (2) chemical substances; (3) infection with the colon bacillus; (4) rarely other infections such as with the pneumococcus and meningococcus.

**Phlegmonous Gastritis.**—It is often difficult to ascertain the cause of gastric abscess and in the case observed by C. Kleineberger (Münch. med. Woch., Aug. 4, 1903), iodide of potassium must be held responsible. A strong man of advanced years receives less than a dram of this drug within three days, for emphysema and chronic bronchitis. Soon severe iodine poisoning makes its appearance and with it, gastro-intestinal disturbances of a serious character followed by peritonitis, collapse and death. At autopsy, the abdomen was found filled with pus and the entire stomach wall was the seat of suppuration. The patient's previous history was negative, especially in reference to the intestinal tract. It follows that in cases of iodism some attention should be given the stomach and gastric lavage may often be indicated.

## SURGERY.

**Traumatic Hydronephrosis.**—A boy, twelve years of age, was struck by a horse's hoof in the left side, and soon after began to vomit, and complained of extreme pain all over the abdomen; urine tinged with blood; the same on the next day. The abdomen was somewhat distended, and tender on pressure, especially on the left side. The patient improved so well in the course of a few days that he was discharged from the hospital to be readmitted, however, in two weeks, with still greater abdominal pain, and a marked swelling occupying the whole of the left costal space. The nature of the swelling—its fluid contents, definite boundaries not disturbed by moving the patient about—suggested to I. G. Ryaboff (Roussky Vratch, No. 30, 1903) a circumscribed collection of fluid in the abdominal cavity, a cyst developed immediately after a trauma with a tendency to rapid enlargement. The anamnestic data, especially as regards the admixture of blood in the urine, pointed to a possible hydronephrosis of the kidney. On performing a nephrotomy, and the fluid having been removed, a soft mass was felt by the examining finger which turned out to be clotted fibrin that closed up tightly the ureter and thus evidently served as the cause of the hydronephrosis. The pelvis was carefully cleaned, and the cut surfaces of the kidney were stitched to the edges of the skin wound, while a drainage tube was introduced into the pelvis connected with a vessel containing a solution of boracic acid. On the fourth day after the operation the stitches that united the edges of the incised kidney to the skin were removed, and a larger drainage tube introduced. During the first few days about 100 c.cm. of urine was excreted through the drainage tube, but by the sixth day this amount diminished to 40 c.cm. The drainage tube was removed on the ninth day, and the opening was soon closed. The first few days only 450 c.cm. of urine were excreted through the urethra, but this quantity soon increased up to 900 to 950 c.cm. The urine was at first turbid, with a considerable sediment, but without any admixture of blood; it gradually cleared up, until it finally became limpid. Temperature was normal all this time. The kidney gradually returned to its former natural size until, before the patient's discharge, it could hardly be palpated. Patient was discharged entirely cured. The rapid and certain success of the operation is due, according to the author, to the permeability of the ureter, which corroborates the view that the hydronephrosis was due to the closure of the ureter by the coagula of fibrin brought on by extravasated blood under the influence of the trauma.

**New Operation for Caput Obstipum.**—Dividing or extirpating the contracted sternocleidomastoid is generally not sufficient to cure a wry-neck, since the opposite muscle is elongated so much that it cannot carry out normal rotation, where the difference between the two muscles is more than four centimeters. L. Wullstein (Centralbl. f. Chirurg., Aug. 15, 1903) shortens the stretched muscle by means of sutures placed beneath the entrance of the spinal accessory nerve. Simple resection is contra-indicated, since the lower portion of the muscle would lose its innervation. The bandage is generally kept on for twenty days, after which slight movements are permitted. The only objection to this method is that two skin incisions are necessary.

**Operation for Femoral Hernia.**—In elderly people and in cases of incarceration, J. Gilli (Centralbl. f. Chirurg., Aug. 8, 1903) modifies Lotheissen's method for femoral hernia as follows: The skin is incised parallel to Poupart's ligament, the lower flap of skin pulled downward and the sac dissected to the edge of the fossa ovalis. This is followed by splitting of the aponeurosis of the external oblique and displacement of Poupart's ligament. A Kocher's sound is then passed upward at the upper edge of the external hernial ring

between sac and plica falciformis, till it appears on the abdominal side of the inguinal ligament, corresponding to the inner hernial ring. Upon this sound the ligament and plica are divided transversely. After all spurting vessels are caught (such as an abnormal obturator artery or a large anastomotic vessel between obturator and inferior epigastric) the thickened fascia propria surrounding the neck is split, when the sac will be completely free. After this the hernia is reduced and the opening closed in the ordinary way. By this method the constricting ring is severed under complete control of the eyes and hemorrhages difficult to check are avoided. By completely unfolding the neck of the sac, the abdominal cavity can be opened above it and its contents tamponed off, before the sac itself is opened, thereby avoiding a peritonitis in strangulation. The operation can be performed under local anesthesia even in sensitive people.

**An Aid to Narcosis in Ileus.**—The question of narcosis in cases of intestinal obstruction and ileus has been attended with many difficulties, chief among which has been the danger of an aspiration pneumonia. Especially in the case of an ileus where operation may have to be undertaken without previous preparation, regurgitated materials may be inspirated even after the stomach has been washed out. The attempt has been made of leaving the stomach tube in situ during the anesthesia, but it was found that the gastric contents passed alongside as well as through it. In order to obviate this difficulty, an ingenious apparatus has been devised by W. KAUSCH (Berl. klin. Woch., August 17, 1903). It consists of a soft rubber stomach tube near the distal extremity of which is fastened a rubber balloon, which when dilated has a diameter of 7 cm. From this leads a thin rubber tube somewhat longer than the stomach tube, which is connected with a similar balloon. This contrivance is introduced into the stomach in the usual way before narcosis is begun, with the balloons collapsed. The latter are then inflated and a clamp placed on the tube beyond the second. The anesthesia is then continued, while sufficient traction is exerted on the affair to keep the inflated balloon at the cardia of the stomach. In three cases of ileus in which the author tried it, a lot of fecal material was discharged through the stomach tube but none alongside which could have possibly entered the larynx. Another advantage claimed for the contrivance is that the upper part of the gut may be cleared of its contents without making an opening, by merely squeezing the contained materials into the stomach, from which they can readily find their way out through the tube. A metal clamp, properly protected with rubber, is placed around the tubes where they come into contact with the teeth, so that compression from the latter is avoided.

**Surgical Treatment of Trifacial Neuralgia.**—A method of treatment which follows closely that of Durante and Thiersch and which combines nerve stretching and resection is thus described by G. BARONI (Gazz. Osped., Aug. 2, 1903). The trigeminal nerve is exposed for as great a length as possible and isolated. The nerve is then seized with pincers at the angle of the wound in the soft parts corresponding to the center of the nerve and gentle traction is exerted upon it. Gradually the nerve is seen to be stretched and drawn outward. It is again seized with the pincers near the angle of the wound and more energetic traction causes it to be severed some distance from the point at which it is held by the forceps. This same maneuver is repeated at the opposite angle of the wound, that is toward the peripheral portion of the nerve. In this manner a larger portion of the nerve is removed than could be accomplished by simple resection; for not only is that part accessible which is uncovered by the incision, but an additional portion is drawn out by the movements of traction and the section occurs nearer the ganglion. Furthermore, the beneficial effect of nerve stretching is attained by the same means through which the section is accomplished and simultaneously with it.

**Murphy Button in Stomach and Gut Operations.**—The interest in this subject remains unabated. In a leading article of almost 100 pages O. NEUWEILER (Archiv f. klin. Chirurgie, Bd. 69, Heft IV, 1903) gives a critical review of all recent literature concluding in this volume the able article of the previous issue. He concludes that perforation resulting from the use of the Murphy button is particularly prone to occur after union of the small gut following resection for incarcerated hernia; in certain gastro-enterostomies and particularly after circular iliocolostomies. In many cases the blame for the perforation lies in faulty technic or in the use of worthless buttons. In hernia, the cause of perforation lies more in the already existing infection than either in bad technic or faulty button. This is shown by the fact that union by suture yields no better result. This is, therefore, no just arraignment of the button principle. Before using a button the following conditions should be fulfilled: (1) The margins of the ring which are designed to hold together the serous surfaces on the male side and all marginal holes must not be sharp but evenly rounded off; (2) the opening between the cylinder and ring of the female side must be wide enough to admit a thick gut wall; (3) the cylinder of the female part must be somewhat shorter than that of the male or that a complete locking of the two parts may be possible; (4) the male cylinder, when the button is closely pressed together should not overreach, lest, with the fingers closely pressed over the openings, its margin may seriously wound the mucous membrane of the gut; (5) the strength of the spring must be such that the pressure will be absolutely continuous so that necrosis will occur early; (6) the size of the button must be in proper relation to the size of the gut. Touching on the technic of inserting the button he notes the following points: (*a*) The purse-string suture should not be placed too far from the edges of the gut lest a cuff result too large to be accommodated by the button; (*b*) Similarly this stitch shall not be placed too near the edge for fear of tearing out when the button is pressed together. Two to three mm. from the edge seem the best average distance; (*c*) In circular anastomoses care must always be taken that the stitch holds the mesentery close to the button so that at this point only serous surfaces shall be brought together; (*d*) Protruding mucous membrane should always be resected; (*e*) The closure of the button should not be accomplished by a single push but by several. The fingers should be so placed as not to wound the mucous membrane upon the margins of the lumen; (*f*) In most cases a protecting reinforcing line of suture should be used.

**End to End Union of Arteries and Veins.**—The literature of this interesting problem is not as yet very full. A valuable contribution to it has been made by GEORG JENSEN (Archiv f. klin. Chirurgie, Bd. 69, Heft IV, 1903) which won for him the gold medal at the University of Copenhagen. His most important conclusion is that in those cases in which union is sought to be established by the use of sutures alone, without the introduction upon the intima of any foreign body, thrombus formation is entirely dependent upon bacterial infection. His experiments were conducted entirely upon horses and goats. He sutured, as a rule, the veins and arteries of the neck. So far as infection went his

results were somewhat discouraging, he having found it very difficult to keep the horses infection-free. He has devised a method of suture which differs somewhat from that of Glück, Murphy and Payr. Upon a ligature of fine silk he threads two needles. As much as 2 cm. of the vessel may have been resected. He consumes but 1 mm. at the end of each segment of vessel in making his stitch. This is a great improvement on other technics. From without in, through all coats, he passes the needles on the proximal side, from within out, on the distal fragment, they are driven 1 mm. from the margin. He used in his primary operations from 12 to 14 of these U-shaped stitches. His most recent modification is simply to pass two such stitches and then complete the sewing of the invaginated parts with a circular stitch. He concludes that in the absence of infection there should be no thrombus formation nor invalidating narrowing of the vessel's lumen.

## HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

**Hemorrhagic Gastritis Due to a Laryngeal Pseudomembrane.**—The specimen demonstrated by A. G. ELLIS (Proc. of the Path. Soc. of Phila., June, 1903) was removed from the body of a child seven months old who had stomatitis and pharyngitis and who died with signs of tuberculous meningitis. At the pylorus there was found a plug of soft material, consisting of fibrin. Removal was easily accomplished but where it had been in contact with the gastric mucosa, the latter was considerably eroded. That this pseudomembrane had been formed in the respiratory passages was proven by the presence of small islets of tissue containing ciliated epithelium. A large number of diphtheria bacilli were also found.

**The Structural Changes of the Pancreas as Related to its Functional Condition in Normal and Spleenless Dogs.**—The histological appearance of the secretory cells of the pancreas, according to G. FICHERA (Beiträge z. Path. Anat., Vol. 34, No. 1), shows in the different stages of digestion and in the fasting condition, the same changes in spleenless as in normal dogs. At the same time the tryptic zymogen is produced irrespective of the presence or absence of the spleen. The islands of Langerhans display in the different periods of digestion functional and morphological changes which are the same in normal and in spleenless dogs; the ablation of the spleen has, therefore, no influence upon the function of the islands. The epithelium of the pancreatic ducts is furnished with the power to secrete. The spleen produces, particularly during the period of digestion, an oxidizing ferment, which during this period is sent in large quantities into the circulation; from this as the result of certain changes in the epithelium of the pancreatic ducts, the ferment passes into their lumen. In the latter it exerts its activity, transforming the pancreatic zymogens and rendering possible the characteristic proteolytic properties of the pancreatic juice. Of extreme interest is the fact that in spleenless dogs the capacity of the epithelium of the pancreatic ducts to secrete is markedly disturbed. In splenectomized dogs the pancreatic juice has no effect on albuminoids, since the removal of the spleen has deprived the above-mentioned secretion of every oxidizing capacity. The pancreatic juice is robbed of its most important and most specific constituent.

**Mechanical Obstacles in the Intestines and the Excretion of Indican.**—The observation made by Jaffe, that obstipation in the small intestine produces a marked increase in the excretion of indican, while a similar condition in the large intestine produces no such increase, is confirmed by A. ELLINGER and W. PRUTZ (Hoppe-Seyler's Zeitschrift, June 19, 1903). An increase of indican accompanying obstipation in the large intestine is to be attributed to an extension of this condition to the smaller gut. The authors believe that no precise diagnosis of the functional capacity or patency of the ileocecal valve is possible without an exact quantitative determination of the indican. The clinical symptoms of intestinal occlusion frequently come on acutely, although some obstacle may have been present in the intestinal canal for some time. It should be the province of clinical investigation to determine whether or not repeated measurements of the indican content would give early knowledge of an increasing stenosis in the gut, at a time when, without such determinations, the slight and uncertain symptoms would only warrant at best a supposition as to the real condition. The researches of the authors prove that the narrowing of small portions of the gut, at least in the dog, produces marked changes in the indican.

**Soap as Disinfectant.**—Green soap has only a slight disinfecting power, according to O. HELLER (Arch. f. Hyg., Vol. 47, No. 3). Combined with crystallized carbolic acid in the proportion of 1 : 3 it forms a solution at room-temperature and increases the disinfecting power of the acid. Typhoid germs are killed by a five-per-cent. solution of phenol, but if green soap is added, a four-per-cent. solution will have the same effect. Soapy solutions of cresol, such as lysol, therefore do not only permit a higher concentration of the relatively non-poisonous cresol, but also make it a better disinfectant. The real cause of this is not yet explained, but possibly a new compound is formed by the interaction of soap and cresol.

**Syphilis in Apes.**—The successful experiment of inoculating syphilis into a chimpanzee after many unsuccessful attempts with other members of the monkey family was reported to the Academy by ROUX and METCHNIKOFF (Gaz. med. de Paris, Aug. 8, 1903). Great bacteriological and therapeutical discoveries are expected from this achievement. Unfortunately large sums are necessary to carry out these experiments, since the chimpanzee is an animal very difficult to capture.

**Tubercle Bacilli in Milk.**—The preliminary report of W. RULLMANN'S experiments upon the effect of prolonged heating at a low temperature upon the tubercle bacilli in milk is found in the Münch. med. Woch., Aug. 4, 1902. It may be stated conclusively that heating for half an hour up to 65° C. does not kill the germs for the inoculated guinea-pigs invariably became tuberculous, even when the milk was thoroughly shaken. Experiments showing the effects of an hour's heating are not yet concluded but it is certain that the milk does not suffer in taste or digestibility by this process.

**Experimental Lead Colic.**—It is impossible to obtain a clear idea of the pathological changes in the ganglion cells of the celiac plexus in lead colic from the studies hitherto published, so that M. MOSSE (Zeitsch f. klin. Med., Vol. 50, Nos. 1 and 2) repeated the experiments on rabbits with an organic salt of lead. Metallic lead was found deposited in the cells and certain pathological changes were noted, but these were also found when other substances which cause contraction of the gut (berberine) were injected. The lesions must therefore be looked upon as resulting from excessive intestinal contraction. They are not characteristic for lead and do not explain the abdominal symptoms.

## SPECTACULAR THERAPEUTICS.

The world of music will probably never know what it lost in the failure of Richard Wagner to supply himself with a pair of American spectacles. This is all the more lamentable in view of the fact that the contributions of America to the art of music have been rather meager, and that if the great Baireuth composer had only used a pair of Yankee eye-glasses, we should have had some right in this country to claim a share in the evolution of his eternal harmonies.

This is now, of course, a vain regret; but if the world of music has lost something, the world of science has gained much: for we owe it to the lucid writings of an American ophthalmologist that genius need no longer be handicapped by the want of appropriate goggles. In fact, genius without its spectacles will probably be as rare hereafter as a day in June, for with the frightful examples before us not only of Wagner but also of Darwin, Huxley and Carlyle, it is safe to say that no man of genius will henceforth be allowed to appear in public with his eyes uncovered. We could no more tolerate it than the Mohammedan could allow his women to go unveiled. The public would probably arise as one man and exclaim to such a rash man of genius: "Remember Wagner, remember Darwin, remember Huxley, and get thee to an ophthalmologist!"

The disadvantages of this state of things may be that some upstarts, who wish to palm themselves off as men of genius, will take to wearing spectacles, and so try to impose upon the world. It might be difficult, in fact, for non-experts to distinguish the musical compositions and scientific monographs of such upstarts; the very fact that these pseudo-genii wore spectacles would be confusing. But we should probably be safe in relying upon the ophthalmologists to give us some test or sign by which we could distinguish the true from the false, for these eye-specialists would doubtless be called upon to examine many more eyes than ever, and if reasonable fees were secured by them, they might establish a critical bureau of their own to announce to the world what are the real and what are the spurious men of genius. We doubt not that it would be easy to select an American ophthalmologist who would be an admirable chief for such an ophthalmological bureau of universal criticism.

The possibilities of good that open before the mind's eye from having all our men of genius wear spectacles are innumerable, and vastly greater than we have time or space to depict. What would not evolution have been by this time if Darwin had only worn specs? Is it too much to claim that he might have discovered the missing link? To what sublimity of style would not Carlyle's scolding have mounted if only he had had a pair of American eye-glasses that were warranted not to fall off his nose? Is it too much to suppose that even Froude, when he wrote the biography of the sage of Chelsea, might have discovered the exact form of insanity from which Mrs. Carlyle suffered, because her husband had asthenopia? What would not Huxley have accomplished with the bench of Anglican bishops if he could have had a better shot at them through a pair of Philadelphia spectacles? Is it too much to believe that he would have turned them all into agnostics, to the lasting satisfaction of himself and the scientific world? What would not society have gained if Wagner could have corrected the acoustics of his presbyopia with a pair of ten dollar lenses with gold rims? Is it too much to suppose that his audiences might get home in time to go to bed before half-past midnight? These are but few—very, very few—of the unspeakable advantages that would have accrued from attending to the refraction of refractory men of genius.

For ophthalmology the gains from this discovery will be ever greater than for the world at large. We do not mean the pecuniary gains, for, of course, these do not enter into consideration; but we mean the elevation of that specialty from being a mere branch of the science of medicine to the supreme height of being an arbiter of the productions of genius and an adjuster of spectacles to the nose of genius itself. This is indeed a destiny.

---

### TUBERCULOSIS IN MAN AND IN ANIMALS.

The widely advertised pronouncement of Koch while in England a few years ago, as to the difference between human and bovine tuberculosis, excited scientific interest all over the world, and caused the foundation of a special Investigation Commission attached to the Berlin Sanitary Bureau. The Commission was greatly assisted in its laudable work by the German authorities, and the results of its labors have been embodied in a report presented the other day by its chief, Prof. Kossel, before the Berlin Medical Society.

The communication treated, first, of the results obtained by the subcutaneous injection of tuberculous virus, derived from pigs and cattle, into cattle. In order to avoid the possibility of mixed infection a pure bouillon culture was employed instead of the matter directly from the infected animal. The site of the inoculation swelled perceptibly, attaining in the course of a few weeks the size of one's palm; on the eighth to tenth day the nearest lymphatic glands became involved, and in many instances attained the size of a child's head. Fever was observed the eighth day after injection. On autopsy the contents of these glands were found to consist of cheesy matter, while the rest of the body contained abundant miliary tubercles.

The experiments with human virus in the form of cultures made from sputum and pulmonary tissue, gave the following results: Both the swelling at the site of inoculation, and the enlargement of the adjacent lymphatic glands were considerably smaller than in the former experiments. At the autopsy of animals four months after inoculation, living bacilli could be detected at the site of the injection, while the contents of the glands consisted of small, circumscribed foci of cheesy matter; no miliary tubercles were found anywhere on the body. Inoculations were also made with bacilli from tuberculous bones, tuberculous cervical glands, and from one case of tuberculosis of the genito-urinary tract.

The sum total of the experiments with human tuberculosis embraced 39 different cultures, 23 from adults and 16 from children. Nineteen of these cultures failed altogether in producing any marked changes in the inoculated animals; nine caused the appearance, in the course of four months, of small infectious foci in the nearest lymphatic glands, but without any further spread of the disease, in seven other cases there was a somewhat more considerable affection of the lymphatics, and only four cases in which the inoculation was made from the virus of children was there noted a general infection. The conclusion drawn was, that notwithstanding Koch's view of the small danger of transferring bovine tuberculosis to man, a few of the cases in which this danger became a reality should serve as a warning against the use of raw milk from infected animals as a food for children.

In the very animated discussions that followed the report, Prof. Orth, Virchow's successor at the Berlin University, called attention to the fact that extreme caution should be exercised in drawing conclusions from observations on the transmission of tuberculosis from animals to man. He referred to the statement of Schütz (Koch's co-worker in the Veterinary Institute) that the pearly distemper of cattle (bovine tuberculosis) may, though very rarely, be transmitted to man. The observation that those working over cadavers of cattle less frequently became affected with what is known as the cadaver tubercles of the hand, than those who perform autopsies on human beings is, according to Orth, due to the fact that cattle in general suffer less from tuberculosis than man. Moreover, it remains yet to be proven that this affection is really of a tuberculous nature. It is quite likely that we have to do here with a form of mixed infection. The differences in the pathological anatomy of tuberculosis in man and that of the pearly distemper in cattle are accounted for by the differences in the anatomical structure, for it is a well-known fact that the same infectious principle presents a different pathological and clinical course in different living beings. It is sufficient to compare tuberculosis in man and in the guinea-pig.

Domesticated animals, such as goats and pigs, are easily susceptible to human tuberculosis, as Schütz himself proved some twenty years ago. Orth inoculated five calves with human tuberculosis, and of these, two fell victims to a severe form of general tuberculosis. The data communicated by the Sanitary Bureau go to show that

ten per cent. of all inoculations of cattle by human tuberculosis resulted in severe forms of the disease; twenty-eight per cent. of the cultures of tubercle bacilli from man turned out to be pathogenetic for cattle. Koch and his followers assert that tuberculosis which is transferred from man to cattle is not human tuberculosis but the "pearl disease." If that be the case, then it is clear that man may become infected from cattle and vice versa, and all the measures adopted hitherto to prevent the spread of the infection from cattle to man must remain in their present force.

The discussion on the subject became so heated that in replying to Prof. Schütz, Dr. Orth was forced to confess his astonishment at the attitude of Koch's followers who have tinctured the question with a peculiarly personal element as if defending the personality of Koch himself. The fame of the great bacteriologist, as Orth well remarked, is so firmly established that it would not suffer a whit even if he acknowledged that he had committed an error; for in scientific questions truth must stand above every other consideration: *Amicus Schütz, amicus Koch, sed magis amica veritas.*

## PROLONGATION OF HUMAN LIFE.

ACCORDING to the last census the average length of human life in the United States had increased during the previous ten years from somewhat less than thirty-two years to nearly thirty-six years. There are those who doubt the value of census statistics in matters of this kind and who consider that many variable factors enter into the problem of vital statistics and that so much improvement has occurred in the gathering of these data in recent years that the results may, after all, mean very little in the concrete and only indicate a better state of knowledge rather than a better state of health. To such doubters it will be interesting to learn that the actuaries of the life insurance companies of the world, in their meeting here in New York, last week, were agreed that there has been a very notable lengthening of the average of human life, during the latter part of the nineteenth century. As on the calculations of their actuaries depends the rate for life insurance which the companies must charge, in order that their business may not be a losing venture, it seems very evident that the lengthening of human life is no mere theoretical consideration but is an actual fact on which serious-minded business men are satisfied to risk money.

A number of communications, read before the meeting, showed that the principal reason for the lengthening of human life is to be found in the lessened death-rate from contagious diseases. Epidemics of cholera, which were a matter of constant recurrence every ten years, if not oftener, in the early part of the nineteenth century, in many cities of the old and new world, are now definitely a thing of the past. Yellow fever is another of the diseases whose mortality has been very decidedly decreased during the last half of the nineteenth century.

It must not be forgotten that cities so far north as Philadelphia, New York, and even Boston, were liable to recurring epidemics of yellow fever, that made great havoc especially among the poorer population. This improvement in vital statistics is undoubtedly permanent and makes the problem of life insurance much simpler than it was even fifty years ago.

It is, however, among children especially that the lessening of the death-rate has brought about a definite increase in the length of life. Children are more likely to contract contagious disease than are adults. The statistics show that in the last thirty years the mortality of such diseases as scarlet fever, whooping-cough, diphtheria and the diarrheal diseases of children have been very materially reduced. Curiously enough the mortality from measles remains nearly the same as it was quite half a century ago. This seems to be because pneumonia is a frequent complication of measles. As is well known, the death-rate from pneumonia has surely not been decreased in recent years and has probably even increased in spite of every effort on the part of medical men and the most careful study of the disease, its possible prevention and methods of treatment. It is in the group of infectious throat diseases that the most striking diminution of mortality has occurred. The death-rate from diphtheria is now probably less than one-third the rate of fifty years ago. Those who are opposed to the use of antitoxin may well read a lesson for themselves in this fact.

As the data become more definite and more complete in recent years the reduction in mortality becomes more evident. Each year of the last decade, for instance, has shown a definite amelioration in the death-rate not only as regards the country at large, but especially as regards city life in various parts of the country. If such widely separated cities as New York and San Francisco, Boston and Savannah, Lowell and Baltimore, Brooklyn and Pittsburg, be considered, it is found that not only during the last five

decades has there been a constant decrease in the city's mortality rate, but that this is especially noticeable in the last decade when the more careful collection of statistics might have made the death-rate appear comparatively higher than in the earlier years, when so much diligence in collecting death reports was not employed. It is very interesting to find that at last there is to be a definite recognition on the part of those outside of the medical profession of how much modern medical science has done to make life less full of suffering as well as actually longer.

A great deal remains to be done, however, for with regard to certain diseases there has been no improvement in the mortality notwithstanding all the advances in medicine. In certain diseases the conditions seem to be actually worse than they were half a century ago, and the death-rate from them is higher. While such city scourges as smallpox, typhoid fever, and tuberculosis are much reduced in mortality, pneumonia has certainly not lost any of its fatality and cancer is actually much more extensively fatal than with past generations. As a matter of fact, cancer at the present time accounts for as many deaths in our cities as do all of the infectious diseases taken together, with the exception of those which affect the respiratory tract. Cancer mortality has more than doubled during the last thirty years. Evidently the studious attention of the present generation must be concentrated upon these maladies if we are to continue the work that the last generation accomplished so successfully. The very fact that while the sanitation of cities has decreased the death-rate for infectious diseases it yet has allowed that from cancer to increase may point to the fact that all of the investigations thus far undertaken with regard to cancer have been misdirected. In any case, this is the problem that must be faced. Let us hope that its successful solution is near at hand.

## ECHOES AND NEWS.

### NEW YORK.

**Opening College of Physicians and Surgeons.**—The opening exercises of the academic year 1903-4 will be held in the Lower Lecture Room on Thursday, September 24, 1903, at three o'clock p. m. After a brief address of welcome by the President of the University an address will be delivered by Walter B. James, M.D., Professor of the practice of Medicine, upon "The Old and the New Medicine."

**Medical School Inspectors Appointed.**—Health Commissioner Lederle appointed recently about 50 physicians to make up the corps of medical school inspectors for this borough. About 25 were appointed for work in the other boroughs. The number of medical school inspectors will be smaller than usual this year because of lack of funds to employ them. They will begin work on September 21.

**New Gouverneur Hospital to Be Completed.**—Plans have been filed with the Building Bureau for the completion of the new Gouverneur Hospital at Gouverneur Slip, running through the block from Front to Water street. The plans provide for the west wing to the present five-story and basement main building, also for a one-story extension into the rear courtyard and for a two-story ambulance station, with a stable, fronting on Front street. The completed building will be of brick, stone and terra cotta, 116 feet front, and have two wings, each 140 feet deep and when finished and equipped will have cost about half a million dollars. The west wing and extension are to cost $250,000 and the ambulance station an additional $25,000.

**Sterile Milk and Infant Mortality.**—The summer pasteurized milk depots maintained by Nathan Straus closed on Saturday, having dispensed more pasteurized (sterilized) milk than in any previous year since the beginning of the work in 1892. Much of the success of the season's work was due to the earnest cooperation of the Health Department. At the beginning of the summer season Dr. Lederle caused cards of instruction as to the proper feeding of infants to be displayed in every tenement in the city. These cards gave the location of all the Straus milk depots, and were in the nature of an educational propaganda making for good health among the tenement dwellers. All the members of the free corps of physicians of the Health Department carried gratuitous coupons for pasteurized milk, which they distributed where needed. These depots will remain open throughout the year: At 151 Avenue C; 45 Monroe street; 241 East Fifty-ninth street, and 235 West Sixtieth street. At these depots all gratuitous coupons will be honored. The depots in the playgrounds of the public schools were a new feature of the charity this year. They were so placed at the request of the Board of Education. The comparatively low death rate prevailing in New York among infants in recent years has caused other large cities to look for the cause, with the result that the present season has also seen the establishment of pasteurized milk dispensaries in Chicago and Philadelphia, modeled after the plans of Mr. Straus in New York. In both these cities Mr. Straus gave the plant for pasteurizing. With the increase from year to year of the amount of pasteurized milk dispensed, a marked and consistent decrease in the death rate of children under five years of age has been noticeable. In 1891 the death rate for children under five years old during June, July and August was 126 per thousand. In 1897 it dropped to 91.3 per thousand. This year it was only 63.6.

**"The Malaria Map."**—Of course, according to the recent explanation of the causation of malaria, this must be in some degree regarded as a misnomer, but that it still exerts a potent influence is very apparent to the real estate agent. The correct and official name of the map is, "A Topographical Map of the City of New York," and it was prepared by the late Gen. Egbert L. Viele for the Council of Hygiene and Public Health of the Citizens' Association in 1865. It has been adopted by the Health Department of New York, and copies of it are to be found framed and hanging on the wall of many physicians' offices. The map shows the Island of Manhattan as it was before the Dutch settlers bought it from the Indians and as it was in 1865. That is to say, underneath the labyrinth of streets are represented the hills and

valleys, the swamps and meadows, the streams and water courses as they were before the leveling hand of the street-maker and house-builder made the whole island a monotonous wilderness of brick, mortar, block pavement, and asphalt. Some of the tales told by this map are revelations to those who know only the New York of to-day. Of course every old New Yorker knows that the Tombs stands on the site of the old Collect Pond, and that Canal street was once the bed of a canal, but how many know that West One Hundred and Sixth street was once the bed of a river, and that the hill between Columbus and Amsterdam avenues is caused by the masonry of the abandoned aqueduct? How many remember now that the territory from Eighty-fifth to Ninety-fourth street, between Central Park West and the Hudson, was once rolling meadow land, and that from Ninety-fourth to One Hundred and Second street was a region of swamps, cut up by numerous small streams? Who can tell now that from One Hundred and Fifth to One Hundred and Eleventh street on the west side was a region of rocks and hills, with brooks and rivulets everywhere, so that, while one house may be on a rock foundation, the next one to it may have a cellar constantly wet from the forgotten brook which flows under it? All the streams of this section were tributary to a good-sized river which flowed into the East river in the neighborhood of Ninety-sixth street. All this is told by the "malaria map." Perhaps this will explain to some landlords why apartments which are cheap and apparently in every way desirable are rejected after a list of streets has been consulted by the prospective tenant.

**Experimental Work at Cornell.**—The Cornell University Medical College in New York City has provided for a Chair of Experimental Pathology and Bacteriology, to carry on research work, independently of the regular instruction given to undergraduates. Dr. B. H. Buxton is to be in charge and will be assisted by Dr. Victor C. Vaughan, Jr. The pathological organic chemistry, so intimately associated with all the problems of disordered metabolism, will be under the direction of Mr. Beebe. This work is to be entirely distinct from all undergraduate or postgraduate instruction and purely for the advancement of scientific knowledge, and is to be conducted in the Loomis Laboratory, a building originally designed especially for this purpose.

## PHILADELPHIA.

**Officers of Cumberland Medical Society.**—At the organization of the Cumberland Valley Medical Society, held at Mount Alto Park, September 8, the following officers were elected: President, Dr. R. W. Ramsey, Chambersburg; Vice-Presidents, Dr. James Elvy Hilser, Carlisle; Dr. T. H. Weagley, Marion; Dr. J. W. Humrichouse, Hagerstown, Md.; Secretary, Dr. J. J. Coffman, Scotland; Assistant Secretaries, Dr. R. A. Mille, Carlisle; Dr. P. B. Montgomery, Chambersburg; Treasurer, Dr. J. H. Montgomery, Chambersburg.

**Charter Obtained by Phipps Institute.**—A charter has been granted to the Henry Phipps Institute for the Study, Treatment, and Prevention of Tuberculosis. The managers of that institution are now in position to purchase property and erect permanent buildings to carry forward the work recently begun in a small way at a temporary location on Pine street. The directors chosen to act for the first year are Henry Phipps, George E. Gordon, of New York, and Dr. Lawrence F. Flick. Amy F. Phipps and Samuel B. Harbison, of Pittsburg, in conjunction with the three directors, are named as subscribers. The site for the permanent location of the institute has not yet been finally selected.

**No Vaccination in Schools.**—The visits to schools by the district vaccine physicians have been discontinued while arrangements for inspection of the children's vaccination marks are being made by the Committee on Hygiene of the Board of Education. It is thought that arrangements can be made whereby all children not vaccinated within five years or having deficient marks may be revaccinated by the family physicians of their parents. The inspection will be made by physicians who are members of the school faculties or by volunteer physicians appointed by the Board. It is understood that the school controllers will in every instance prohibit the vaccination of pupils in school buildings.

**Marriage of Dr. Flexner.**—The marriage of Dr. Simon Flexner and Miss Helen Thomas, of Bryn Mawr, took place on Thursday, September 17. Miss Thomas is a sister of Miss M. Carey Thomas, President of Bryn Mawr College.

## CHICAGO.

**American Association of Obstetricians and Gynecologists.**—The sixteenth annual meeting of this Association will be held in this city September 22, 23, and 24. Arrangements are being made by the local committee for the entertainment of the Fellows and their guests. The sessions will be held in the law library of the Northwestern University Building, corner Dearborn and Lake streets.

**Incorporation of Pasteur Institute.**—The Chicago Pasteur Institute has been incorporated by A. P. Lagorio, Carlotta Lagorio, and B. G. Bruno, with a capital stock of $2,000 to treat hydrophobia.

**Willard Hospital Buys Land.**—The Francis E. Willard National Temperance Hospital has purchased property at 349 Lincoln street, for $1,500. It is 24x115 feet and is 338 feet north of West Polk street.

**Diphtheria.**—The prevalence of this disease during the week has resulted in seven children being excluded from the W. K. Sullivan School. At least five of them are believed to be suffering from the disease, while the other two are known to have been exposed. All the children excluded from school have lived in dwellings where the disease prevailed. The children were prevented from entering the school through the activity of Superintendent Bodine of the Compulsory Education Department and Dr. Allen with several assistants. The work of the inspectors will continue until all signs of the disease disappear from that vicinity.

**Tour of Inspection by Sanitary Experts.**—Sanitary experts representing the State of Illinois and the Sanitary District will leave Chicago Sept. 16, on a tour of inspection of the Illinois water way via the drainage canal and the Illinois River from Chicago to St. Louis. Their purpose is to prepare the evidence for Illinois to be submitted at the hearing of the sanitary case between the States of Illinois and Missouri, which is to open in this city Sept. 21. Missouri claims that the drainage canal is a menace to the health of the people of Missouri in general and St. Louis in particular, by contaminating the water supply. In the party will be Prof. Long, of Northwest University; Profs. Palmer and Burroughs, of the University of Illinois; Prof. Jordan, of the University of Chicago; Dr. Adolph Gehrmann; W. P. Mason, a noted sanitary engineer of New York; H. L. Russell, of the University of Wisconsin; E. G. Smith, of Beloit College; L. C. Kinnecott, of the

Worcester Polytechnic; Rudolph Hering, head of the Hering Commission, which made the pioneer investigation of Chicago sewage, on which the canal project was founded, and Dr. Reynolds, Commissioner of Health of Chicago. The experts will devote five days to the trip. They will observe conditions of overflow, the backwaters of the various dams along the river, the color of the water at different points, and comparative sanitary conditions below and above Peoria. They will note the improvement of the river from Chicago to Peoria and the effect on the river caused by Peoria sewage, arising from cattlesheds, distilleries, glucose refineries, stockyards, slaughter houses and gas houses and manufacturing establishments.

**Disposal of City Refuse.**—The disposal of garbage has become a very important question in this city. Complaints have been made that in some wards the appropriations for the work of collection of garbage were so small that the work might have to be abandoned. In reference to the system of carting the refuse to open dumps, this has always been reprehensible, and, owing to the growth of the city, should not now be tolerated. It means the maintenance of a most obnoxious nuisance. It is interesting to note that many cities have and are in favor of garbage cremation or reduction plants. We give here the names of some of the cities with the method of treatment employed: Boston, reduction; Buffalo, reduction; New York, reduction; Philadelphia, reduction; Washington, reduction; Louisville, cremation; Cincinnati, reduction; Cleveland, reduction; Detroit, reduction; Milwaukee, cremation; Minneapolis, cremation; St. Louis, reduction; San Francisco, cremation. The list is a rebuke to Chicago, but greater instruction will be found in a municipal year book, which is published in England. This gives us a glimpse of municipalities at work, which shows that we are merely in the kindergarten stage in this country. Speaking of the cleansing department of Manchester, the book says: "For the year ended March, 1902, it dealt with 370,877 tons of refuse, consisting of night soil, street sweepings, market, slaughter-house trading refuse and contents of pail closets. The department is a great manufacturing concern; it makes manure, oil, soap, tallow, mortar; it has two large estates of 3,681 acres, upon which part of the refuse of the city is disposed of, and has workshops where it makes implements, vans, railway trucks, brushes, machines, etc. Nearly 2,000 men are employed by the department, which has over 400 horses and 500 vans and carts. Refuse which cannot be utilized is burned in destructors." When such an elaborate system as this is compared with the crude makeshift to which Chicago resorts, the difference seems almost as great as the difference between a savage and a civilized state of society. The aldermen who are now investigating the subject should realize how far Chicago is behind, and strive at least to make a good beginning.

**Mortality Rate.**—The average August death-rate of the ten years (1893-1902 inclusive) was 16.37 per thousand of population per annum. For August, 1903, the 2,255 deaths reported gave an annual rate of 14.07 per thousand, or 16 per cent. less than the ten-year average, and the lowest August mortality rate on record. The chief reduction is in the deaths under five years and in those from the acute intestinal diseases, from typhoid fever and from whooping cough to which the low temperature and the good sanitary quality of the water contributed. There were 185 fewer deaths from the impure water diseases than in August, 1902. On the other hand, the deaths from diseases especially affecting adult male life all show an increase over last year. The excess of male over female deaths is 27.7 per cent.

**Duty of Injured Persons in Employment of Physicians.**—The Appellate Court of Illinois for the Fourth District holds in C. and E. I. R.R. Co. vs. Burridge, a personal injury case, brought by the latter party, that an instruction stated the law correctly which told the jury that it was the duty of the party suing "to employ such doctor or doctors for the treatment of his injuries as ordinary prudence in his situation at the time of the injury and thereafter required; and to use ordinary judgment and care in so doing, and to select only such doctor as was of at least ordinary skill and care in his profession; but the law does not make him an insurer in such case that the doctor will be guilty of no negligence, error in judgment, or want of care, and where such errors or mistakes occur in the treatment, the injury resulting from such mistakes is properly regarded as part of the immediate and direct damages resulting from the injury."

**Milk for Schools.**—The children in the Chicago public schools will no longer have to drink impure water, if a proposal of the Milk Commission meets with the approval of the Board of Education. Pasteurized milk, on sale at a cent a bottle at every school, is the solution of the problem suggested by the commission. At the Thomas Hoyne school, where the pasteurizing plant is located, the water has been shut off from the building while some repairs have been in progress. More than 300 three-ounce bottles were taken in the course of the day.

## GENERAL.

**Trichinosis in Germany.**—Last week we noted the occurrence of two hundred cases of trichinosis at Homburg. Forty cases are now reported at Neustadt, near Coburg. Some of them have proven of a severe and dangerous type.

**Appointment of Dr. Hutchings.**—The State Commission in Lunacy has appointed Dr. Richard H. Hutchings medical superintendent of the St. Lawrence State Hospital at Ogdensburg, N. Y., in succession to Dr. William Mabon, who recently accepted the post of general superintendent of the New York City hospitals.

**Yellow Fever.**—The State Health Officer of Texas, received telegraphic reports from Dr. I. P. Sessions, whom he sent to Mexico to investigate the yellow fever situation, stating that the disease had appeared at Monterey. According to official statements from the Yucatan Government there were 128 cases of yellow fever in the city of Merida during August of which fifty proved fatal. In Progreso during the same time there were nine cases, but no deaths.

**The Plague at Marseilles.**—A number of buildings on the outskirts of this city, where suspected cases of bubonic plague had been reported, were destroyed by fire to-day. The sanitary officials used sulphur in the disinfection of merchandise in the buildings, and the flames were communicated to the buildings themselves. Only the walls were left standing. The unofficial reports make the situation serious. The dead, it appears, are four women and two men, whose bodies were covered with buboes, leaving little doubt as to the nature of the disease. Eighteen suspects, including four infants, are under surveillance. Three undoubted cases have been admitted to the hospital. The vessel which brought the cargo of rags has been isolated. Other rigid sanitary

measures have been adopted, and it is believed that the authorities desired the removal of the burned buildings as an additional precaution. The local authorities at Genoa have quarantined against Marseilles.

**Enlarge Naval Hospital.**—Surgeon Gen. Rixey has decided to urge on Congress the enlargement of the General Naval Hospital at Portsmouth, Va. The institution now has 200 beds, and he will recommend that it be enlarged so as to accommodate 500. Two modern wings will be erected in rear of the present structure, and a third wing will connect these. There will be isolation wards and every modern convenience. A new steam generating plant and a pest house will form part of the scheme of improvement. Dr. Rixey states that as Portsmouth is to be one of the largest naval stations in America, the facilities for the care of the sick and wounded must of necessity keep pace with the growth of the naval establishment in size and importance.

**Income of the French Physician.**—There are a few physicians in Paris with incomes of $40,000 to $60,000. The average income of French physicians, however, is only $550 a year, or $720 in Paris. Yet, whereas the number of medical men is rapidly decreasing in Germany and Austria, it is still increasing in France. In 1901 there were 2,000 fewer than there are now, though the population was about the same.

**Convenient Device.**—A novel dose-indicator for medicine bottles which has been recently put on the market consists of a disc of cardboard on which is printed the hours of the day in much the same manner as the dial of a timepiece, with the hours divided into quarters. In the upper part of this device there is a loop designed to be fastened around the neck of the bottle and which holds the dial suspended prominently on the side of the bottle. As one dose of medicine is disposed of the exact time of the next one is indicated by moving a clip along to the proper point.

**Cholera in Syria.**—Cholera is reported to be raging fiercely at Birejik, Syria. Birejik is a town of ten thousand inhabitants on the left bank of the Euphrates, at the head of navigation.

**The Prize Essay of the American Medical Association.**—The American Medical Association offers annually a gold medal, value of $100 for the best essay on any subject relating to medicine or surgery. The recipient of this prize will be given the option of the gold medal, or a bronze replica of the medal, and the balance of the appropriation (about $90) in money; or the entire amount ($100) in money. Inasmuch as the Association annually sets apart the sum of $500 for original research, this prize is offered to stimulate the production of a superior practical paper based either upon experimental studies or clinical investigation, or both. The Committee will give preference to papers having the greatest brevity consistent with thorough consideration of the subject, and recommends that the paper shall not exceed 5,000 words. The Committee, while not restricting the choice of subjects, recommends as an important subject for consideration "The Therapeutic Value of the Digestive Ferments." Competing essays must be type-written, and bear no mark revealing their authorship; but instead of the name of the author there must appear on each essay a motto, and accompanying each essay a sealed envelope containing the name of the author and bearing on its outer surface the motto of identification. No envelope will be opened by the Committee until a decision has been reached as to the most deserving essay. The other essays will be returned to their respective authors. The Committee reserves the right to reject all essays, if none are found worthy of the Association medal. Competing essays must be in the hands of the Chairman of the Committee not later than April 1, 1904. Lewis S. McMurtry, Louisville, Ky., Chairman; Burnside Foster, St. Paul, Minn.; M. H. Fussell, Philadelphia, Pa., Committee.

**Cancer Caused Pope's Death.**—Drs. Lapponi and Mazzoni, the physicians of the late Pope Leo, have published a defence against the attacks made upon them by Dr. Cardarelli, who practically charged that they had made a wrong diagnosis of the Pope's disease, and declared that he died of pulmonary cancer instead of pleurisy or pleuro-pneumonia. Both physicians say that they detected the true nature of the Pope's illness, but Cardinal Rampolla, the Papal Secretary of State, objected to having it made public. When the symptoms became clearer they insisted upon being allowed to protect their reputations against easily foreseen criticism, but Cardinal Rampolla was immovable. He even refused to have it announced that a third operation of thoracentesis had been performed, although Drs. Lapponi and Mazzoni did perform such an operation. The physicians, therefore, wrote in the presence of a witness a full history of the case, giving the real nature of the disease. Copies of the statement were given to Cardinal Rampolla and the major domo of the Vatican.

**Fighting to Keep Out Smallpox.**—The State Health Department is urging extraordinary precautions against a smallpox epidemic in the town of Hoosick and the village of Hoosick Falls. There are more than a dozen cases at Bennington, Vt., which is connected by trolley line with the Hoosick neighborhood. No cases have yet crossed the State line, and it is hoped that general vaccination will prevent spreading the disease.

## CORRESPONDENCE.

### AN IMPOSTER.

*To the Editor of* MEDICAL NEWS:

DEAR SIR: Permit me through the medium of your valuable journal to warn the profession concerning a young man who pretends to be my nephew, and on various pretexts secures money, mostly, I regret to say, from my personal friends. I have no nephew by the name of Musser, and know of no one who dare use my name in any scheme whatsoever.

I should add, Mr. P. Corzelius, representing the American Medical Association, has a letter from me, as well as other means of identity, for the purpose of carrying on his work. Yours very truly,

J. H. MUSSER.

1927 Chestnut St., Philadelphia, Sept. 11, 1903.

### THE HISTORY OF THE DISTRIBUTION OF STERILIZED MILK TO TENEMENT HOUSE CHILDREN IN NEW YORK.

*To the Editor of the* MEDICAL NEWS:

DEAR SIR: In an article on the subject of infant mortality, by Dr. Rowland G. Freeman, in the MEDICAL NEWS of September 5, 1903, the following statement occurs, speaking of the distribution of milk, or as the

author says, a "suitable nutriment to the bottle-fed babies of the tenements;" by this we must all understand pasteurized or sterilized milk.

"New York City owes to Nathan Straus a great debt of gratitude for *inaugurating* or *carrying out*, at his own expense, this most valuable aid to its tenement house babies."

The facts in connection with the inauguration and distribution of good and fit milk to the children of the poor, are as follows:

The main idea of distributing milk, suitable for infant feeding, among the poor of the tenement districts of New York, originated with the author of this communication. After having been in charge of the children's class of the Good Samaritan Dispensary, then the Eastern, for some time, and noticing from year to year the futile attempts to treat the gastro-intestinal disturbances of infancy and childhood during the summer months, without the aid of a suitable nutriment, I began to agitate the placing within the reach of the sick poor children of a nutriment which was not only suitable (modified), but which could not easily be rendered unfit for the infant, as regards acidity and bacterial content. I began the distribution of bottles of sterilized milk to sick infants in May, 1890. At this time the scheme was rather discouraged, because as one physician, a chairman of one of our societies, said, the washing of the bottles would be the chief obstacle. Undaunted, however, I constructed apparatus, and after much labor, opened my laboratory, such as it was, in the summer of 1890. I presented the apparatus before the County Medical Society in May, 1890, and before the Pediatric Section of the Academy, in November of the same year, I read a paper embodying my experiences. That summer I had only supplied 134 infants with 7,000 bottles of sterilized modified milk, but it was a beginning. Mrs. Felix Adler, through her physician, Dr. Richard Stein, heard of my efforts to reach the poor children, and seeing I was handicapped by lack of funds, she organized a committee of ladies, the first of its kind, to establish a large plant which would furnish sterilized milk to tenement house babies. This improved laboratory was opened in 1891, and from June 15 to October 15, 1891, 575 children were fed with 40,000 bottles of sterilized milk. I then began to try to reduce the temperature of sterilization, and found 85° C., or 185° F., consistent with safety, instead of 100° C., or 212° F. My results were again published in the *New York Medical Journal*, October 15, 1891. In the year 1892 to 1893, we supplied 1268 children with 97,000 bottles of this milk, sterilized at this low temperature. Two years before this we had established two sub-stations for sterilized milk, one at Jungmann's pharmacy, Sixtieth street, and another in Harlem. Our funds gave out in the subsequent year, and we devoted our energies to our own dispensary plant, where the demand was most pressing. About this time, 1893, Mr. Straus sent his representative, Mr. Kinkead, to my laboratory, saw our work, and I also gave him a note to Dr. T. M. Rotch, of Boston, who had at that time established the Walker-Gordon Laboratory. Mr. Straus received and adopted many suggestions as to the washing and sterilizing of bottles, also corking, which he adopted in his first plant, and which he was then about to open. His representative saw me several times, and also listened to my papers read before the Academy. To be concise:

In 1894 we distributed about 150,000 bottles, whereas all the Straus depots distributed 300,000.

In the year 1899, the ninth to tenth year of our existence, I was feeding a daily average of 200 children and giving away 379,776 bottles of milk a year, sometimes pasteurized, others sterilized, according to the weather. This is more than half the number distributed by Mr. Straus' many depots in the same year. Today the laboratory I first established is feeding on an average of 200 babies of the tenements daily with milk, either sterilized or pasteurized, according to the exigencies of the weather, and the directions of the physicians. I may say that, from the very start, my idea was only to give the milk on a prescription from a physician, which has always been done. This is the only orderly way of distributing milk for infant feeding.

I have in the above given a succinct history of the inception, the inauguration and the success of the main idea of giving the poor sick children of New York the milk, their life food, in a form in accordance with scientific advances of infant feeding. In doing this I am actuated by the same motives I was in the inception of the affair. The credit of this method of feeding the poor belongs to the writer of this communication, who, at the sacrifice of labor which cannot be estimated, and his own means, carried it to completion. Let no one think that I do not appreciate the wise and philanthropic efforts of one of our most respected lay citizens; far from it, and glory to him; but to the medical profession and to us here in New York, belongs the credit of the whole idea and its successful operation to-day. More especially should the profession take unto itself the credit of this idea, inasmuch as, in the year in which the decline of mortality is shown by Dr. Freeman, to be decided, the Good Samaritan Dispensary laboratory, under my guidance, was contributing to the infants of a most densely crowded tenement district, more than half as many bottles of sterilized milk as the whole aggregate of the Straus depots (600,000).

692 Madison Ave.,
New York, Sept. 8, 1903.

Henry Koplik, M.D.

## TRANSACTIONS OF FOREIGN SOCIETIES.

### German.

**Tendoplasty.**—The German Society for Orthopedic Surgery, Second Congress, held in Berlin, June 2, 1903, was opened by Vulpius, who presented a paper on tendoplasty, based upon his own extensive experience with 400 cases. Most methods employed for elongating tendons are followed by good results. The newly formed tissue is fibrous and later becomes tendinous if hemorrhage and infection do not occur. Tendons are best shortened by means of partial excision or suture. An atrophic muscle may thus regain its function by overdistention and loose joints can be rendered firm. Tendon transplantation is a more difficult operation; the speaker's own method or the periosteal or transosteal modifications all give good results. Silk tendons to fill in gaps are recommended only where no other method is possible. Peripheral paralyses are most amenable to treatment, but in poliomyelitis, Little's disease and apoplectic hemiplegia much improvement is often seen. Arthogenous contracture of the knee-joint, congenital clubfoot and flatfoot will often yield to transplantation. Defects in tendons may be treated by using a neighboring tendon or by implanting human or animal tendons or pieces of silk or catgut.

F. Lange prefers total transplantation in the leg, since the function will be more perfect than where only part of an adjoining tendon is used. He uses his method where more than three muscles are paralytic and discusses new points of insertion to restore the most perfect functions. Where periosteal transplantation is indicated, the sutures are also passed through the ligaments and cartilage, to give the tendon a better hold. Silk is to be preferred here, and abscesses are avoided

by draining for forty-eight hours. Three silk tendons were demonstrated, which had functionated for two and three years and which were surrounded and permeated by tendinous tissue.

In the discussion which followed SCHANZ recommended aluminium-bronze as suture material. WITTEK has attempted to transplant the ileopsoas so that it will act as extensor. VULPIUS also praises total transplantation, but states that this method cannot always be resorted to.

**Treatment of Fractures.**—A paper on the treatment of fractures implicating joints by means of extension and orthopedic procedures was read by BARDENHEUER.

**Spondylitic Curvature of the Spine.**—FINK treats spondylitic curvature of the spine by horizontal position in plaster of Paris, aided by strips of cotton applied crosswise under the deformity. After about a year the patients begin to wear a corset.

**Coxa Vara.**—The etiology and forms of congenital and acquired coxa vara were discussed by JOACHIMSTHAL. BORCHARDT looks upon a traumatic separation of the epiphysis as real cause, while FROHLICH detected the *Staphylococcus albus* in the bone-marrow of two cases, and ascribes the deformity to early, chronic osteomyelitis. Good results are obtained according to CODIVILLA from osteotomy in the neighborhood of the trochanter with fixation of the shaft in abduction.

The final papers were read by BADE, who improved the corset for scoliosis by a rubber bag on its inner side, which can be inflated, and by SPITZY, whose clinical and anatomical investigations show that the newly born never possess flat feet.

## SOCIETY PROCEEDINGS.

### BRITISH MEDICAL ASSOCIATION.

*Seventy-first Annual Meeting, Held in Swansea, July 28, 29, 30 and 31, 1903.*

(Continued from Page 528.)

**The Methods at Present in Vogue for the Reduction of the Dislocation.**—"I shall confine myself to the measures at present employed, and I shall also deal only with those that aim at the reduction of the dislocation, without wasting time on the question of apparatus and orthopedic appliances. It may fairly be said at the present time that all cases of a suitable age should be submitted to some form of operative treatment, and that those who are over that age will probably get on better without apparatus than with it; there seems to be no really satisfactory apparatus in use, nor, indeed, does it seem likely that such a thing could be designed. In discussing the question of the methods employed for the reduction of the dislocation, the foremost place, at any rate on the ground of priority, belongs to the operative procedure commonly known as the 'Hoffa-Lorenz' method, which is still practised by so well-known an authority as Professor Hoffa, or at all events was advocated by him so recently as the Thirteenth International Medical Congress held at Paris in 1900.

**The Hoffa-Lorenz Operation.**—"The steps of the operation are briefly as follows: The patient is anesthetized, and full extension is made until the trochanter is nearly on a level with Nélaton's line. While full extension is maintained, an incision is made parallel with the anterior margin of the great trochanter, and one-quarter of an inch in front of it and commencing at its upper angle.

"The fascia lata is fully opened up, the gluteus medius and minimus are retracted, and the capsule of the hip-joint is opened by an incision made upon the neck of the bone while the assistant, who still keeps up extension, abducts and rotates out the limb in order to facilitate this. The capsule is slit up right to its insertion into the rim of the acetabulum, and, if this does not allow the head of the bone to come well up into the wound, the incision in the capsule is made T-shaped by a second incision parallel to the anterior intertrochanteric line. The finger is then introduced into the acetabulum, which is deepened with a gouge or a sharp spoon. Hoffa lays stress on the new acetabulum being made circular, with deep and overhanging edges, especially above. This new acetabulum is fashioned, partly by deepening the old one and partly by gouging away bone from its upper and outer rim. The head is now replaced in the acetabulum, chiefly by traction, and if necessary is trimmed until it fits it. The wound is left open, and is packed with gauze. Outside this a plaster-of-Paris spica is applied, while the assistant maintains the extension and also keeps the limb in a position of abduction and slight inward rotation. The child is finally placed in a Phelp's box. The limb is kept in plaster for three or four weeks, at the end of which the child has electrical treatment and gymnastic exercises daily, with special attention to the abduction movements.

"There are several objections to this method, any of which are sufficient to put it out of court as a routine treatment for congenital dislocation. Indeed, Hoffa himself realizes this, and only advocates the operation for cases in which Lorenz's 'bloodless method' has failed, or for children beyond the age at which the latter method is likely to be successful. The great objection is the risk of anchylosis which is likely to follow the extensive interference with the joint surfaces; this risk is still further increased by Hoffa's plan of leaving the wound open and stuffing it with gauze. This latter procedure, which Hoffa advocates in order to minimize the risk of sepsis, I believe to be quite unnecessary, but even without it the risk of anchylosis is necessarily great. Whenever both articular surfaces are denuded of their cartilaginous covering, especially in a young child, anchylosis, generally of a severe type, is almost certain to follow even in spite of vigorous passive movement.

**Burghard's Method.**—"In order to overcome the difficulties presented by this operation, and at the same time to ensure the true reduction of the dislocation, I have been in the habit for some years past of practising an operation that combines to some extent the more important features of the 'bloodless method' with the certainty of the open operation. The real merit of Lorenz's so-called 'bloodless method' is not that it is bloodless—for that is its weak point—but that it calls attention to two facts that must receive adequate treatment if success is to be obtained. The first fact is that the chief obstacle to reduction, as far as the muscles are concerned, lies in the shortening of the adductors, and the second is that after reduction the only stable position for the limb in the majority of cases is one of extreme abduction. These two important points I utilize in the following operation.

"At a preliminary sitting, under full anesthesia, the adductors are either fully stretched or are divided with a tenotome; the procedure in fact is so far similar to the 'bloodless method' which will be described immediately. If reduction is effected by these means well and good; the limb is then put up as in Lorenz's method, and the results are checked by skiagraphy. Should reduction by these means fail, or should reluxation occur, the hip-joint is exposed at a second sitting, a week later, by an incision from just below the anterior superior iliac spine in the interval between the sartorius and the tensor fasciæ femoris, and the capsule is exposed as for excision and slit up fully, the head of the bone pro-

truded, and the finger introduced into the acetabulum; the ligamentum teres, if present, is cut away. The head of the bone is now guided into the acetabulum by the finger already introduced into it by manipulations closely resembling those in the 'bloodless method,' and when this is accomplished it will generally be found that the limb spontaneously assumes a position of marked abduction and of outward rotation, although the latter position is not at all constant; indeed, where the angle of femoral torsion is very great there will be rotation inward. As a rule I divide the tendon of the iliopsoas obliquely with a pair of blunt-pointed scissors introduced into the wound, as I have found it a powerful agent in inducing reluxation.

"The exact method of incising the capsule is not of much importance: latterly I have made it parallel to the long axis of the neck of the femur and over the head of the bone made prominent by rotating the limb outwards. This has the advantage that the incision is in the lax portion of the capsule and allows the thickened anterior portion lying over the acetabulum to be more easily defined. It is this latter portion of the capsule that offers the greatest obstacle to reduction; the finger passed through the narrow slit-like opening between it and the upper edge of the acetabulum will ascertain whether there is room for the head to pass into position, and if not, a way must be made for it by detaching the capsule from the acetabular rim sufficiently to allow of its passage. It is always well, however, not to detach the capsule too freely from the rim of the acetabulum as the various bands in that situation are powerful agents in preventing the head of the bone from slipping out of place. No attempt whatever is made to deepen the acetabulum or to shape the head of the bone afresh. There has been no difficulty in getting the head of the bone into the acetabulum in any of the cases operated upon by this method; its exact position is determined by the finger in the wound, and there can be no mistake. In order to maintain the head of the bone in position—which is really the hard part of the procedure—a portion of the lax capsule above the acetabulum is excised by an elliptical incision and the cut edges are brought together with stout catgut sutures. The capacity of the capsule is thus diminished and the joint is rendered more stable. The deeper tissues are finally approximated with catgut sutures and the skin wound is closed without drainage. The operation can be done through an incision about 3 inches in length, and there is practically no bleeding; if more room be required it is easy to curve the incision outward above and to detach part of the origin of the tensor fasciæ femoris from the iliac bone.

"All that now remains to be done is to put up the limb in a suitable immobilization apparatus. At first I employed a modification of Croft's plaster-of-Paris splint, so designed that the wound could be inspected at any time without disturbing the parts, but more recently I have simply put up the limb in a plaster spica, taking in the knee. The Croft's splint was used to avoid the risk of suppuration beneath a fixed plaster bandage; but, as such a thing has never occurred in any of my cases, the ordinary plaster spica is now applied from the first, and allowed to remain undisturbed for three weeks, when it is removed with a Gigli's saw under anesthesia, the stitches taken out, and a fresh spica applied. An X-ray photograph is taken at the same time, and, should the head of the bone be found to have slipped out of place, the wound is opened up and reduction again effected. The position in which the limb is put up in the first instance depends entirely upon the position of maximum stability. In all cases there is one position in which the limb remains without reluxation occurring, and this is the position chosen. It is nearly always the fully abducted position, generally with some outward rotation but often with inward rotation. I have had cases in which the only stable position was that of full extension and rotation inward. The after-treatment corresponds almost exactly to that for the 'bloodless method' except that it takes rather a shorter time. The results will be discussed in connection with those of the latter method.

**Lorenz's "Bloodless Method."**—"The patient is fully anesthetized and the adductor muscles are first fully stretched or torn through subcutaneously by striking them repeatedly with the ulnar border of the hand while the limb is forcibly abducted. At first the abduction obtained is limited, but as the rupture of the muscles goes on it increases until the limb is abducted through 90 degrees. During this the assistant steadies the pelvis, pressing down the sound side of the pelvis. Should there be much shortening, horizontal traction upon the limb may be made to bring the trochanter down to the level of Nélaton's line, but this is rarely necessary.

"When the parts have thus been fully stretched, reduction of the dislocation is effected by vertical extension, that is, traction upon the limb flexed at right angles to the pelvis. At the same time direct pressure is made over the great trochanter, and, as the extension is reaching its full limit, the limb is carried outwards, that is, abducted through a right angle. By these maneuvers the head of the bone is made to pass forward over the posterior lip of the acetabulum—an event marked by a loud and characteristic click—until it lies over the acetabular depression. In order to fix the head here the limb is put up in a position of abduction, carried if necessary as far as 90 degrees, and at the same time hyperextended and rotated slightly inward. In this position it is kept for four or five months by a plaster spica that does not take in the knee; at the end of this time a second spica is applied after the limb has been brought into a position of moderate abduction combined with a slight degree of flexion and this is kept on for another four or five months, during which time the child is encouraged to walk as much as possible, so that the pressure of the head of the bone against the acetabulum may deepen and develop the latter.

**Discussion of the Value of the Foregoing Methods.**—"This difficult subject has been aided somewhat by the X-rays. It is now easy to be exact in speaking of the results of treatment, and it is no longer possible to speak of a case as 'cured' when a radiograph shows that the head of the bone is out of place. To this latter category must undoubtedly be relegated a large number of the 'cures' of past years. In future no case can be considered 'cured' unless a radiograph shows the head of the bone in a normal acetabulum, which itself has undergone development and is practically indistinguishable in shape and size and position from its fellow. I could show several cases in which the gait is practically perfect and which most observers would pass as true cures, but in which a radiograph shows the head of the bone above and behind the acetabulum. In speaking of cures among my own cases I mean true cures in the anatomical sense of the term.

"For convenience, the results obtained by any of the foregoing methods of reduction may be divided into three groups: the first is the true anatomical cure in which the affected joint is indistinguishable from the sound one; the second is the group of 'improvements' in which the joint, though not anatomically correct, is nevertheless stable; the gait is markedly improved, and the lordosis is absent, although shortening persists.

Here the head of the bone usually makes for itself a new acetabulum, partly out of the old one and partly out of the ilium above and behind it. Finally, there is the group of failures in which the head of the bone resumes its position on the dorsum ilii, where it slips about as before. By some writers these three groups have been classified as (1) reposition; (2) transposition; and (3) recurrence.

"Great divergence of opinion exists among writers as to the proportion of cases to be allotted to the first two of these groups. There should be no possibility of doubt as to the question of a true radical cure now that radiography is so universally applicable. A glance at a radiographic print will show the difference between a true and a partial cure. When the cure is a true anatomical one the head of the bone lies in the center of the acetabulum; however small or ill-developed the cavity may be, the clear space denoting the Y-cartilage in the acetabulum can always be seen, and the center of the globular head should be directly opposite that. The Y-cartilage is the most reliable landmark in determining whether the head of the bone is in its normal position; the others may be fallacious, owing to the position in which the limb is put up. Should the center of the head lie above the Y-cartilage it is certain that the head, although possibly lying to some extent in the acetabulum, nevertheless does not do so entirely, and that the new joint surface is formed partly at the expense of the old one and partly from the outer surface of the ilium.

It will be obvious from what has gone before that there are fewer difficulties in the way of a true reduction of the dislocation if the attempt be made after opening the joint than if it be made by the 'bloodless method,' and that therefore in order to prove their case the advocates of the latter must be able to point either to better results or to diminished risk. The first and most serious difficulty peculiar to the bloodless method is the covering-in of the acetabulum by the anterior part of the capsule or 'the capsular hymen' that has already been referred to more than once. If the slit-like opening into the acetabulum be too small for the head of the femur to pass through—as in my experience it often is—it is absolutely impossible to obtain true reduction by any mere manipulations: nothing short of an open operation will do. And the chances of the surgeon being confronted with this difficulty must increase with the age of the child, for, as we have seen, the obliteration of the acetabular cavity by the thickened anterior part of the capsule tends to increase as the patient's age advances, so that, even if reduction could be effected at an early age, it may be mechanically impossible by manipulation later on in life. From this it follows that, if Lorenz's method is to be adopted, it should always be done as early as possible after the child has become sufficiently clean to allow the necessary plaster bandages to be worn.

"Another drawback that must have struck those who have had much practice with the 'bloodless method' is the difficulty of being sure when the head of the bone is in the acetabulum. This point does not seem to have attracted the attention it deserves, for the difficulty is a very real one, even in experienced hands. It is true that the head of the bone gives a loud click as it passes over the posterior rim of the cavity, but it is easy, as I have repeatedly proved when performing the open operation, to obtain both the loud characteristic click and the stable limb without the head of the bone being in the acetabulum at all; what happens, at any rate in some cases, is that the head rides forward over the posterior acetabular rim, and then jumps to a position above and behind the joint where it is held in an apparently stable position by the extreme abduction that is being practised at the same time. In other cases there is already a shallow ridge of bone thrown out to bound the new acetabulum, and it is this that the head of the femur jumps, and it is into the newly-formed false joint that the head is reduced, being held in a stable position by jamming it against the ilium by the extreme abduction. This also I have actually verified more than once upon the operating table.

"Hallopeau presented to the Anatomical Society of Paris the dissection of the left hip of a child 2½ years old, who died of bronchopneumonia thirteen days after an attempt to reduce a congenital dislocation by the 'bloodless method,' and he sums up his observations by saying 'It would therefore have been quite useless to expect a bony point of support from the bloodless reduction of this dislocation.'

"It is common experience that great improvement follows the open or the bloodless method in the majority of cases provided that the patient is of a suitable age. The question of the durability of the improvement, however, or, in other words whether a false joint formed as a result of the operation is permanently stable or not, is one upon which little reliable information is at present forthcoming. The reason for this is that in the first place the operation—bloodless or open—has hardly been practised long enough to allow of its ultimate results being accurately gauged, and, moreover, attention is chiefly devoted to the 'cures,' while, in the second place, patients are very apt to pass from the surgeon's notice after a time; it is hardly likely that they would keep themselves under observation from early childhood to adult life, as is necessary if the true permanence of the 'improvement' is to be tested. It is a point to which particular attention must be directed in the future.

"And now, having pointed out the anatomical difficulties that lie in the path of true success with the 'bloodless method,' let me turn to the 'cures' claimed for it by those who practise it. Here we meet with a most extraordinary discrepancy in results and some considerable vagueness in language. Thus, Lorenz says that half of his cases are unsatisfactory from the anatomical point of view, and are to a certain extent failures. This he attributes chiefly to alterations in the neck of the femur, rendering it impossible to get the head of the bone in place without putting the limb in a position incompatible with ability to walk. He says, however, that even these cases are much improved by the new and stable joint. As to the anatomical cures, he remarks: 'In many cases the acetabular cavity enlarges and deepens concentrically, so that we can look upon it as a true anatomical restoration of the joint. In the majority, however, the acetabulum enlarges eccentrically by a new formation of bone along its upper border, beneath which the head of the bone remains firmly applied.' These latter cases clearly fall into the second group outlined above, and of course cannot be looked upon as true anatomical cures.

"As to the question of the relative safety of the various methods. It is true that Hoffa, in giving the results of his experience of the Hoffa-Lorenz operative method, says that he had 7 deaths in 248 cases directly traceable to the operation. These, however, were all from faulty asepsis in the earlier cases, and in the last 132 cases there has been no death. Indeed, the question of risk from the open operation that I have described above may be dismissed as trivial. The operation is easy; there is no shock even in the youngest subjects; the operation is practically bloodless, and occupies only a short time. On the other hand the list of accidents that may be laid to the credit of the 'blood-

less method' is a large one, although no fatality has occurred in connection with it as far as I know. Thus there may be severe shock; the femur may be fractured at either end or in the shaft; a very large hematoma may require incision and drainage; edema of the limb may occur, or severe lymphangitis; the sciatic nerve has been known to have been permanently paralyzed. Thus the 'bloodless method' is by no means free from risks, even in very skilled hands, and I venture therefore to suggest that at any rate it should not be advocated to the exclusion of other and more precise methods.

"My own practice is to make a careful trial of Lorenz's method, in the first instance, in all cases under five years of age, and to check the results by radiography. If this does not show a true anatomical cure, I proceed to open the joint and deal with the dislocation in the manner already described; and so convinced am I of the freedom from danger that I do not hesitate to reopen the wound and reduce the dislocation afresh should it be found during the course of treatment that the head of the bone has escaped from the acetabulum; I have done this on two occasions with perfectly satisfactory results. Occasionally I try the Lorenz manipulations a second time if the patient be quite young—say under three years of age—and if the joint be quite mobile and with little shortening, as these cases are most suited for Lorenz's method. When, however, the child is near five years of age, and one careful attempt has failed, I do not waste time further, but open the joint at once. When the child is over five the chances of success by manipulation are much less, and I rarely spend much time over it. The manipulations are used here more as a preliminary to operative interference, and I would advise that, unless the head of the bone clearly goes into the acetabulum during them, time should not be consumed in an attempt that is almost certain to be futile, but that the open operation should be performed in a week's time.

"Bilateral cases are admittedly difficult to treat by manipulation. I believe that much time will be saved and much more good will be done by performing an open operation upon both sides at an interval of, say, three months.

"My own results I may summarize as follows: Lorenz's 'bloodless method' I have tried in 30 cases; in only one of them was a perfect cure obtained, and this case was a child under three years of age. In the remaining 29 some were submitted later to an operation, but all of those who for any reason were not, were very much improved as to gait and general usefulness, two or three of them being so much improved that they would, in the absence of radiography, have easily passed for cured. The only accident that has occurred to me in performing this method was a partial separation—or rather, a mere loosening, for the radiograph showed no separation—of the lower epiphysis of the femur in one case. This did not interfere at all with the progress of the treatment. I have performed the open operation that I have already described in 13 cases. In 9 the cure has been perfect, and the children are now walking about quite well; in 3 the head of the bone has escaped and has formed a new acetabulum above and behind the old, but the joints are quite stable—in other words, these are transpositions; 1 case is still under treatment; and in no case has there been complete failure. I do not therefore recommend the open operation as an infallible cure for these cases; but as a method that is safe and at the same time more likely to produce a precise result than mere manipulations. At the worst, if it fails to cure, it gives a result as good as the latter.

"The following conclusions are drawn from the foregoing considerations: (1) That all cases should be checked by radiography, and that no 'cure' should be spoken of that is not a true anatomical cure. (2) That all cases of congenital dislocation under fourteen years of age should be submitted to treatment. In the great majority improvement will result, while in some a true anatomical cure is brought about. (3) That in all these cases Lorenz's manipulations should be tried in the first instance. Even should they fail to effect reduction they facilitate any subsequent procedures. (4) That the prospect of a cure by Lorenz's 'bloodless method' is in direct proportion to the youth of the child, and that after the age of four years there is little hope of a true cure by its means. (5) That in any case the chances of a true cure by the 'bloodless method' are not very great. (6) That an open operation should be done whenever a radiograph shows that the 'bloodless method' has failed to reduce the dislocation, except perhaps in the case of a very young child—under three years—in whom the manipulations may be repeated. (7) That with the open operation no fear need be entertained of shock, bleeding, or sepsis. (8) That under no circumstances should the joint surfaces be remodeled. (9) That an open operation is more calculated to result in a cure as it enables the surgeon to ascertain beyond a doubt when the head of the bone is really in the acetabulum. (10) That the open operation is especially suited for cases over four years of age and for those of bilateral dislocation. (11) That after the operation the limb should be put up in the position of maximum stability; in the majority of cases this will be similar to Lorenz's position. The limb should be put up in plaster-of-Paris immediately and the casing should take in the flexed knee; this is essential in order to ensure stability of the head of the bone. (12) That all tense structures should be stretched or tenotomized as a preliminary measure a week or so previously to the open operation. The after-treatment is practically identical with that of the Lorenz method."

Mr. Noble Smith showed radiographs of 4 cases, one double in a girl aged six years, one single in a girl aged 11½ years, one single in a girl aged twelve years, and another single in a young lady aged 17½ years. These cases had been operated upon by Lorenz's method since he had seen Professor Lorenz operate in this country. In all these cases a fairly good result had up to this time been attained, although we had still to wait to see what the ultimate results would be. As regards the comparative value of the two forms of operation, he (Mr. Noble Smith) held an open mind, and so long as he could obtain good results, as in the cases shown, he would be content to depend upon operation without opening the joint. In this respect he was in accord with Mr. Burghard. He felt personally much indebted to Dr. Lorenz, because since seeing him operate he found he had succeeded far more satisfactorily than he had done when depending upon Lorenz's written description. He had operated on other cases but these four were the only ones in which he had obtained radiographs of the conditions before and after operation. He had said that the results were fairly satisfactory, but he must add the words considering the ages of the patients. In the six-year-old child the period of six months had elapsed, and he had removed the splint, and had found the joints working quite well, but still held in a very flexed and abducted position; this partial fixation was doubtless beneficial as regards the ultimate perfection of the joints. In the child aged 11½ years the position was very good, but it appeared from the radiograph that the head of the femur had

become detached; he did not think that this would prevent a good result. In the twelve-year-old child a perfect position appeared to have been attained. In the girl of 17½ years he had preceded the operation by many months of stretching and extending the joint. He had succeeded even in this case in placing the head of the femur in a natural position, but there had been a great tendency for the head to slip backward, and the radiograph showed that the head was behind the acetabulum, but at the same time there was no tendency for that head of bone to pass upward. He thought he had succeeded since then in replacing the head perfectly. Mr. Noble Smith also referred to another case of double displacement in a six-year-old girl, in whom he had no difficulty in reducing one joint, but on the other side he had not been able to obtain a perfect result, because the head of the femur could not be placed sufficiently forward. However, he thought that practically even under such circumstances a good result might be anticipated.

Mr. R. C. Dun said: "My experience of Lorenz's bloodless method has been limited to 4 cases. The first of these was reduced, some two months before Professor Lorenz's visit to this country, and the position obtained was not completely satisfactory. I learned much in watching Lorenz himself, and studying his methods of manipulation and subsequent fixation—particularly did I learn the importance of thorough stretching of the anterior part of the capsule of the joint after the reposition of the head. It is, of course, too early to say what the ultimate result in these cases may be. Undoubtedly improvement is generally evident when the child first begins to walk; it has yet to be proved whether such improvement is permanent. I have found that the employment of thin aluminium strips, incorporated with the plaster casing, materially diminishes its weight, and enables the patient to get about more readily."

Mr. Robert Jones said: "I believe that more than one way exists for the cure of congenital hip, and that the same method will not suit all. More good will come from a study of the causes of failure than from the most carefully compiled statistics. For years we have tried methods which have yielded an occasional success, such as extension and abduction in abduction frame, osteotomy of the neck to correct antiversion, manipulations for reductions, and various forms of operation procedure. Neither the Hoffa nor the Lorenz modification appeals to me, as stripping a joint of its cartilage and whittling the head of the femur directly makes for an anchylosing arthrodesis. The essential difference between the methods of Paci and Lorenz is in the recognition by Lorenz of the rudimentary character of the acetabulum and the necessity of enlarging it by direct pressure of bone. In support of the probability of this occurring I may mention that in a boy aged seventeen years, in whom I exsected the head of the femur for a traumatic dislocation, I found an excellent attempt at the formation of a joint. Until the visit of Lorenz I had no idea of the thoroughness of his manipulations, and I at once saw why so many failures had occurred in this country. Since his visit I have operated on 38 cases, 34 of which were reduced, as confirmed by palpation and X-ray photographs. In 4 cases the neck of the femur was fractured, and the shafts transposed anteriorly. These were only complications, and with an increase of experience I think they should not occur. The causes of failure in reduction were folds of capsule between the acetabulum and femoral head, sometimes constriction of the capsule, the importance of which was overrated, anteversion of the neck, and instability of the articulation, due either to a faulty head or rudimentary acetabulum. Of immense clinical importance is the question, 'Can these defects be recognized clinically?' In reply, I think that on completion of reduction one can prognose whether it will be permanent or not. If the hip in the act of being reduced gives the sensation experienced in the reduction of a traumatic case, and if there is stability after reduction, the prospects are good, and the prospects are moderate in those cases where reduction becomes stable after stretching the anterior portion of the capsule by prolonged extension of the abducted hip. Failure may safely be prognosed when the femur slips out of joint on the slightest provocation. In this last variety, exploratory incision is called for to correct soft structure obstruction, or to correct anteversion of the femoral neck. Anteversion can be diagnosed by radiography, as well as by palpation. If operation is done I strongly advocate incision after the dislocation is reduced, and if anteversion exists, the performance of osteotomy of the shaft of the femur, the neck being held in position by pins as recommended by Schede and Bradford. The statistics of the open and bloodless methods are in the hands of the two greatest authorities, Lorenz and Hoffa, about 50 per cent. of cures. This is sufficient proof that there is considerable overlapping, and that the majority of cases operated upon by Hoffa would be simply manipulated by Lorenz. I agree with Mr. Burghard that it is best not to denude the cartilage, but in the worst cases, where operation is most called for on account of anatomical misfits, how is the head to be retained short of excavation? In view of the diverse opinions, I intend to persevere with the Lorenz method as a routine, operating only in the exceptional case, and after a sufficient lapse of time shall form my own conclusions with regard to final results."

Mr. A. H. Tubby said: "With reference to the method of forcible reduction, according to Lorenz's method, we have not at present any means by which we can be quite sure that when the head of the femur appears to have been reduced into its proper place there is no infolding of the capsule or interposition of the capsule between the bones owing to the action of the tense iliopsoas. In fact it seems to me that the data on which an estimation of the condition of the parts may be made, both before and after reduction, are somewhat vague. Neither tactile examination nor the use of the X-rays can be relied upon to tell us exactly what the true state of affairs is. I have not had the opportunity of seeing Lorenz operate, but I am far from being satisfied that an entirely successful method of treatment has been found, even for young children. The risks are not inconsiderable. Fractures of the thigh, tearing of the sciatic nerve, rupture of the femoral artery, and gangrene and death have occurred. In fact it seems to me that the risks of this forcible procedure are as great if not greater than those appertaining to the open method, which may be summed up by the word 'sepsis.' Doubtless while each case should be treated on its merits, it is well, as far as possible, for every surgeon to adopt a line of treatment which promises to him the best results. I have been successful, so far as the certain reduction of the dislocation is concerned in recent cases, by first exsecting a portion of the adductor muscles, and of the sartorius and tensor vaginæ femoris, and then placing the limb or limbs in full abduction and extension for six weeks. Then the joint was opened by the anterior method and the resistant parts of the capsule divided, and by manipulation the head was reduced. The incision in the capsule was closed by suture, and the edges of the skin wound brought together and the limb placed in full abduction and retained there in plaster-of-Paris. I intend to treat

a number of suitable cases in this way, and shall be happy to report on them in three years' time. Indeed, I feel that such a course is imperative in the present condition of treatment of congenital displacement of the hip."

Mr. Burghard, in closing, thanked the speakers for giving their valuable personal experience. He regretted that the subject had been brought up so soon after the visit of Professor Lorenz had attracted special attention to the matter, so that sufficient time had scarcely elapsed for much reliable information to have been gained. He trusted that in a few years' time there would be another opportunity of contrasting the later results of the various methods of treatment. What was wanted for the true elucidation of this very difficult question was not an advocacy of one method to the exclusion of all others, but a series of cases by careful observers who were not concerned to advocate the method, but to state the facts. The question as to the permanence of the results must be the point to which attention should be directed most particularly in the immediate future. He still held strongly to the view that no one method was likely to succeed in all cases.

**Splenomegaly in Infants and Young Children.**—Dr. George Carpenter said that enlargement of the spleen is not an uncommon manifestation in early childhood, and it is frequently found enlarged in infancy. The clinical material which has passed through his hands during the last few years at the Evelina and the North-Eastern Hospitals for Children comprises 348 cases in whom the spleen was enlarged, as determined by palpation, from all causes during the first twelve years of life, cases such as are commonly found in out-patient hospital practice, and which have not been selected.

Dr. Edmund Cautley asked what Dr. Carpenter meant by splenomegaly. Did he include all cases in which the spleen could be felt? It certainly seemed so, judging by the fact that such a large number of cases had come under Dr. Carpenter's notice, and that no less than 163 were infants under one year of age, and as many as 320 out of the total of 348 were infants under eighteen months of age. Dr. Cautley suggested that the spleen was so easily felt in infants under six months on account of anatomical peculiarities, and in infants from six to eighteen months on account of rachitic deformity, that it might readily be supposed to be enlarged. He noted, also, that of the 57 cases associated with syphilis, 31 were infants under three months of age, and that of 60 associated with chronic snuffles, 32 were infants under six months. He thought that undue weight was laid on snuffles in out-patient practice as a sign of syphilis, and he regarded craniotabes as rarely due to syphilis, and commonly caused by errors in diet. In his experience the craniotabes described by Elsässer was very rare. It did not follow that a spleen, felt as enlarged in an infant, was of serious import from a diagnostic or prognostic point of view.

**On the Utilization of Infants' Milk Dépôts.**—Dr. T. D. Lister said: "This question involves a matter of direct interest to those who have to practise among the children for whom the dépôts are primarily intended. Those who have to treat the children of very poor and very ignorant parents, or the children of mothers whose employment necessitates a certain amount of child neglect, have to face continually certain difficulties which infants' milk dépôts are designed to overcome. For the wealthier classes no such difficulties exist.

"When the mother is able and willing to feed her child herself, these difficulties of treatment are minimized, for natural feeding and maternal care are the normal preventives of infantile mortality. But it is impossible to be blind to the fact that hand-fed infants form an increasing proportion of the whole infant population. The chief difficulties met with in feeding such children among the poor arise from bad milk supply, ignorance, and lack of facilities for the proper preparation of food. Broadly speaking, as we all know, they are associated with the use of improper bottles, contaminated milk (contamination occurring both in transit and at home), and milk substitutes.

"We are, as a profession, agreed that cow's milk forms the only practicable basis for hand feeding, that it should be pure and fresh and not overtreated either chemically or by cooking, and that the simpler the bottle and teat the better. I do not know what method of meeting these requirements on a large scale can be devised better than this system of infants' milk dépôts. It is recognized by public health authorities that such a system eliminates the many dangers arising from contamination by carelessness either in transit or at home, both of which—and especially the latter—have been proved to be fertile causes of infant mortality, and that it prevents the use of the many abominable milk substitutes that one constantly sees in the infants' dietary. Moreover, it has always been successful in those towns in this country where it has been tried, and there is a very large experience of its success abroad.

"No system of diminished impurity of the fresh milk supply will get over the difficulties of home contamination and carelessness, and those arising from the use of milk substitutes and impoverished milks among a certain class. The system of "certified milk" proposed by Dr. Coutts is very desirable so far as the ordinary milk supply for infant feeding is concerned, but it does not meet the special needs of those among whom infantile mortality from bad hand feeding reaches its highest point.

"It has been pointed out, notably by Dr. Peyroux, that there is a danger of the encouragement of hand feeding at the cost of maternal responsibility under the usual conditions of management of such dépôts. What I wish therefore to bring before you is that it is our duty to lend all our influence and assistance in counteracting this as well as other dangers in the use of milk dépôts. To say that any system of hand-feeding of children, whether "percentage" and other scientific methods, or the simpler methods used in milk dépôts, is as good as natural feeding is to be a contributory to child slaughter. Professor Rotch, who is probably the best living authority on the cow's milk feeding of children, said that no method yet devised was equal to that of Nature.

"Other objections have been raised from time to time to the establishment of infants' milk dépôts, as, for instance, that the method of feeding is not an ideal one. I do not think we need worry about that when the most scientific methods are said by their authors not to satisfy this condition. Infantile mortality among hand-fed children, so far as it may be diminished by careful feeding, is the matter requiring our immediate attention.

"How is this medical supervision of the infants to be secured without affecting the control of the dépôt by the health authorities, and how are we to secure milk dépôts where they are most wanted? To secure effective results they must be placed where they are wanted, and they must be used where they are placed. It is obviously only by the cooperation of the various interests that these results can be achieved, and it is for this cooperation that I think we should work.

"With these pledges of support from institutions dealing with a very large number of necessitous infants the success of a dépôt in their immediate neighborhood is already assured, and the borough council has decided

in favor of the establishment of a dépôt. As I have said, it does not matter to us as a profession where the funds come from to furnish the dépôts. That is a matter for local opinion. There is no doubt that the action of the Local Government Board auditors in disallowing the expenses of the Battersea milk dépôt will soon lead to a clear decision as to the powers of district councils in this matter, but where the district council does not care to undertake the work itself there is no reason why, having once obtained the support of the medical profession in the district, it should not afford information and facilities to charitable bodies on the one hand, or contractors on the other hand to enable them to carry out this necessary work in the districts where it will be most useful. As a mere matter of personal opinion I believe this to be so important a branch of preventive medicine that, properly guarded against abuse by the cooperation of medical practitioners, it should be undertaken by the municipal authorities. That such dépôts would be also of great advantage to us as practitioners in securing a definite method of feeding infants under one year of age carefully and exactly is undeniable in relation to the class for whom we want it. Moreover, their educational influence as to the care required in feeding children would not be the least of their advantages. Example is better than precept, and I anticipate better results from the milk dépôt than from the feeding leaflet.

"All I can claim for the suggestion is that such a method of cooperation would largely remove the objections that have been raised to the establishment and use of infants' dépôts by showing that the infants fed in them were under medical supervision, and that they were believed to be necessary and useful by the medical men in the districts where similar resolutions to those I have mentioned are adopted. It is a confusion of interests which prevents this work being done, and it is a coordination of interests which seems to me, as far as medical interests alone are concerned, likely to help toward its accomplishment."

Dr. Edmund Cautley, in discussing Dr. Lister's paper, said that the question raised by Dr. Lister was of both economic and political importance. He objected to the scheme on the ground that it tended to pauperize the poor, to render them less likely to carry out their proper duties to their children, and because there could be no guarantee that the particular milk would suit the particular child. To carry out the scheme efficiently would require a resident medical officer at the dépôt, constant modification of the food, and systematic weighing of the infants. Even if the scheme were a success, he feared it would then lead to an increase in the neglect of suckling, and ultimately prove injurious It was by no means accepted as an axiom by experts in this country that percentage feeding was the best system for the artificial feeding of infants. He thought it quite the wrong way of attacking the question of infant feeding among the poor. The mothers should be taught, and, in his own experience, they would learn, if they wished to rear their children. If they did not, the scheme proposed would have little or no effect. The most that municipal authorities should do was, in his opinion, to secure a proper supervision of the milk supply, and to provide a clean good milk, which could be obtained by the very poor on a written order from a medical man.

**Discussion on Tuberculosis in Children: Its Relation to Bovine Tuberculosis.**—Dr. Nathan Raw said: "The relation of tubercle bacillus to the many and varied diseases which attack children is not yet thoroughly understood, but I am inclined to think it plays a much more prominent part than we are disposed to believe. What concerns me most in the study of this most difficult problem is, To what extent are these tuberculous lesions produced by cow's milk?

"Professor Koch, the greatest authority on tuberculosis, holds the view that human and bovine tuberculosis are separate and disinct diseases, and that bovine tuberculosis could not be conveyed to the human.

"With the latter part of this statement, I beg in all humility to differ from Professor Koch, and I will endeavor to lay before you my reasons for believing that bovine tuberculosis is frequently conveyed to children by means of milk, and is the cause of a considerable mortality.

"Now it must be admitted that the great body of experimental evidence is in favor of Koch's first contention that the two diseases are distinct, and that it is almost impossible to produce a general tuberculous infection in cattle by inoculating them with human bacilli from sputum. But it does not necessarily follow that because human bacilli have a low virulence for cattle that therefore bovine bacilli have only a slight pathogenic power for man, especially when we consider that bovine bacilli are not only virulent for cattle, but for various other animals, such as the rabbit, horse, dog, pig, and sheep. It therefore appears reasonable to suppose they would be virulent to man, since it is a fact that 'all the disease-producing bacteria that are common to all the domesticated animals are also pathogenic to man' (McFadyean). In short, Koch argues that bovine tuberculosis, being a distinct disease from human tuberculosis, cannot produce the human variety in the body.

"With this view I agree, but I am of opinion that man is attacked by two distinct varieties of tubercle, one conveyed by infection from one person to another, the other by receiving into the body bovine bacilli in milk or meat.

**Two Varieties of Tubercle.**—"During the last few years I have had under observation over 2,000 cases of phthisis pulmonalis, and I have been particularly impressed with the fact that the tuberculous process is nearly always confined strictly to the lungs. The patient usually gives a history, first of cough, then of expectoration; the disease often progresses to death, and the necropsy reveals destructive lesions of the lungs, and nothing more. Out of these cases of phthisis pulmonalis I have only seen the glands and the joints affected in 8 cases, and in the late stages one sees the intestine and peritoneum involved. Phthisis pulmonalis is essentially a disease of young adult life. It is rare to see it as a primary affection under the age of twelve years, the great majority of deaths taking place between the ages of thirty and forty years. On the other hand, strumous or tuberculous joints, enlarged glands, spinal disease, and abdominal tuberculosis with tabes mesenterica, are essentially diseases of infancy and childhood, and are only rarely seen in adult life. I have given particular attention to the clinical manifestations of these various tuberculous affections, and it is rare to see a patient with enlarged glands, strumous joints, or spinal disease develop true phthisis pulmonalis. In fact, clinically they appear to be antagonistic to each other, attacking the body at quite different periods of life, and exhibiting generally opposite symptoms. There are at the present time 118 cases of phthisis pulmonalis in the hospital, and in no case is there any other gross tuberculous lesion present which would certainly be the case if they were all caused by one identical bacillus which would be free to be conveyed all over the body.

"Again, I have had the opportunity of seeing over 500 necropsies on cases of tuberculosis, and I have noticed that even the lungs are attacked by two distinct va-

rieties of tuberculosis—one of a slow and insidious nature, the other rapid and acute, and generally associated with tubercle in other parts of the body. If one compares the appearances seen in cattle dying with tuberculosis with those of children dying of tabes mesenterica and abdominal tubercle, the almost exact counterpart is seen; in fact, as Creighton observes, there is an exact mimicry of disease.

"From these general clinical and pathological observations I am inclined to think that primary intestinal tuberculosis, tabes mesenterica, and other tuberculous affections of the serous membranes in children are probably bovine tuberculosis conveyed by milk, and are not related to human tuberculosis, although the bacillus of Koch is found in them all, and is indistinguishable.

**Tabes Mesenterica.**—"Now let us take first of all tabes mesenterica. By this disease we mean what is popularly called 'consumption of the bowels,' and is one of the most common forms of abdominal tuberculosis in children.

"Infants and children suffer from tuberculosis of the intestines and glands, but it is perhaps more common before the age of two years than afterward. In 103 consecutive necropsies of children dying of tuberculosis at the Manchester Children's Hospital, there was tuberculous ulceration of the intestine in 62, cheesy mesenteric glands in 71, and both ulcers and cheesy glands in 55, tuberculous glands without ulcers of intestine in 7. Ashby states that in at least 70 per cent. of children dying of tuberculous disease of the mesenteric glands was present, and in rather more than 55 per cent. tuberculous ulceration was associated with it, and, he wisely says, primary tuberculosis of the intestine is suggestive of infection by means of tubercle bacilli taken in milk from a tuberculous cow. The figures at the Great Ormond Street Children's Hospital, London, are as follows: In 254 tuberculous children examined post mortem, 151, or 59 per cent., showed cheesy mesenteric glands, and Dr. Still found that in 29 per cent. of cases of tuberculosis in children, primary infection had taken place through the intestine. Woodhead records 127 cases of fatal tuberculosis in children, with involvement of the mesenteric glands in 100.

"My own experience of this affection coincides with these figures, and of 273 cases which I have diagnosed clinically as tabes mesenterica, only 38 have come to post mortem.

"I grant it is extremely difficult to exactly diagnose the onset of tabes mesenterica, and it is not to be assumed that a great many of the cases of diarrhea, wasting, and general inanition in children are tuberculous, as they certainly are not; but I believe that tabes mesenterica is a great deal more common than is generally supposed, and, what is more, a great number of children who receive a mild infection, which is confined to the mesenteric glands, recover absolutely. I have seen this frequently in the hospital, where enlarged palpable mesenteric glands have slowly subsided, and under proper treatment the child has quite recovered. In 5 cases in which I have opened the abdomen during life for hernia and other abdominal disorders I have seen the mesenteric glands much enlarged and apparently cheesy, with sometimes nodules on the peritoneum, yet these children were not suspected of being tuberculous, and they all left the hospital well. Many other surgeons and physicians will be able to confirm this point. Assuming these mesenteric glands to be tuberculous, the question arises, How do the tubercle bacilli find their entrance?

"This difficult problem cannot be proved like an ordinary scientific experiment, since it is impossible to inoculate the human being, and I sincerely hope it will never be attempted. But by carefully considering all the known facts bearing on the question, we ought to be able to find an answer which in all human probability will be approximately accurate.

**Tabes Mesenterica and Milk.**—"I claim your indulgence when I attempt to lay before you all the evidence which I can in support of my view that tabes mesenterica is caused by bovine tubercle bacilli in milk.

"If we consider for a moment the remarkable diminution in human phthisis during the last fifty years, amounting to over 45 per cent., we would naturally expect that other forms of tuberculosis would have fallen in the same ratio were they all caused by the same bacillus. But this is not so; on the contrary, the death rate from abdominal tuberculosis in children as shown by Sir Richard Thorne-Thorne, has greatly increased, amounting to over 20 per cent., and, what is more significant, tuberculosis in English cattle is rapidly increasing.

"Veterinary authorities, such as Nocard, Bang, Dollar, and McFadyean, agree that about 20 per cent. of dairy cattle suffer from tuberculosis, and recent official figures from different parts of England show that in London dairies 25 per cent., in Edinburgh 40 per cent., Midlothian 23 per cent., Durham 19 per cent., and Yorkshire 25 per cent. of the cows are tuberculous.

"If, however, every tuberculous cow produced milk containing living tubercle bacilli, the whole community would be in danger; but it is now generally admitted by experts that only cows wth a tuberculous affection of the udder are really dangerous, and the percentage of such cases is very small, only amounting to 2 or 3 per cent. I have made most careful inquiries during the last five years, and I have never seen a case of tabes mesenterica which had not been fed for some weeks or months on cow's milk. This I consider a most significant fact.

"With a view to excluding infection from parents or family at home I have made a most careful inquiry on this point, and of the 34 deaths only one child had a phthisical parent, so that the probability of infection in this direction is extremely small.

"Now, it is argued by some observers that the tubercle bacilli are not primarily introduced into the body through the mesenteric glands, but that these become affected later on from some other part. If this is so, I ask, How is it that adults suffering from phthisis do not become affected in the mesenteric glands in the same way? It is a fact that they rarely do so, and it is very unusual to see the mesenteric glands affected in phthisis pulmonalis, except as a late affection following secondary intestinal ulceration.

**Similarity of Bovine and Abdominal Tuberculosis in Children.**—"The next link in the chain is the clinical history of a case of tabes mesenterica. In a Poor-law infirmary we often see the child from the commencement of the illness—chronic intestinal catarrh, with diarrhea of offensive yellow stools, with perhaps streaks of blood, a general wasting, and distention of the abdomen. I have examined very carefully several such cases, and have invariably found the chest quite healthy in the early stages of the illness. As the disease slowly progresses, and the atrophy and wasting consequent on the diseased mesenteric glands continues, the general tuberculous symptoms are more pronounced, the temperature becomes hectic, the child begins to cough, and on examination the lungs are found to be tuberculous, and the child invariably dies. The point I wish to make is this: The infection commences in the mesenteric glands from the intestine, slowly spreads to the retroperitoneal glands, then through the diaphragm to the glands in the posterior mediastinum, and finally to the lungs. If the child

lives long enough the brain may be affected too. At the necropsy this process has been corroborated again and again, and I have a case where there was extensive caseation of the mesenteric, retroperitoneal, and portal glands, and only a few grey tubercles at the base of both lungs.

"In nine cases the lungs have not been attacked at all, the disease being confined to the abdomen. If we compare the course of this infection with that seen in the calf which is fed on tuberculous milk, we see an exact mimicry of the disease in every detail. The direction of the lymph stream would certainly be strongly in favor of infection from the intestine to the thoracic organs.

"Passing from the clinical to the bacteriological side of the question, we know that if the various tuberculous lesions in the body are carefully examined the bacillus of Koch is usually found, and, in my opinion, this has led to error in assuming that we were dealing with one bacillus. Koch has shown, I think conclusively, that human and bovine tuberculosis are distinct diseases, but the bacillus of both is morphologically identical and cannot be distinguished under the microscope.

**Probable Non-identity of the Bacilli.**—"On the other hand, the cultures of the two diseases are different, and Professor Ravenal, of Philadelphia, affirms that 'the tubercle bacillus from bovine sources has in culture fairly constant and persistent peculiarities of growth and morphology by which it may tentatively be differentiated from that ordinarily found in man.'

"From a recent case of tabes mesenterica I made cultivations of the mesenteric gland on blood serum with glycerin, and to my surprise the growth exactly corresponded to bovine tuberculosis or Perlsucht. Again from a strumous knee-joint I made a cultivation from the interior fluids of the joint, with an exactly similar result.

"I also inoculated two young heifers with the tuberculous material from a case of advanced hip-joint disease and advanced disease of the knee-joint. They both got thin and wasted, and after four months were killed. At the necropsy there was found in each animal an extensive involvement of the mesenteric glands but no affection of the viscera. Tubercle bacilli were found in the glands of each heifer.

"The experiments recently reported in the British *Medical Journal* by MacFadyean and McConkey are most interesting, and show that active tubercle bacilli are present in a large number of cases not suspected of being tuberculous.

"'The experiments have shown that in the non-tuberculous cases, virulent tubercle bacilli were present to the extent of 25 per cent. The tubercle bacilli, it appears from these experiments, are present much more frequently in the mesenteric glands than ordinary necropsies would lead one to suppose.' This evidence strongly supports the view that I have for a long time held: That a great many children receive a mild infection of mesenteric tuberculosis through cow's milk, and recover absolutely, the infection getting no further than the glands.

**Tuberculous Peritonitis.**—"We have all seen cases of tuberculous peritonitis completely recover after opening and draining the abdomen, and nothing more. So far no satisfactory explanation of this result has been given.

"My opinion is that it is a localized bovine tuberculosis which has died out, and that relief of the fluid is sufficient to cure the patient. Taking all these facts into consideration, I am of opinion that bovine tuberculosis is very virulent for children, and is accountable for tabes mesenterica and other varieties of abdominal tuberculosis; in fact, I believe it to be more virulent for children than human tuberculosis.

"In arriving at this conclusion I lay great stress on the fact that, out of nearly 300 cases of tabes mesenterica observed during the last twelve years, I have never known one to occur in a child which had been fed strictly on the breast, the whole of them, without exception, having been reared on cow's milk for some considerable period.

**Scrofula.**—"We all know now that scrofula, so-called, is nothing more or less than tuberculosis of the lymphatic glands, but is it human tuberculosis?

"I must confess to a difficulty in understanding how it is that these local tuberculous lesions such as enlarged glands in the neck, pulpy joints, and caries of the spine should generally develop in childhood, and in the majority of cases recover and never be heard of again. For it must be admitted that these cases rarely develop tuberculosis of the lung excepting in the process of a general infection.

**Nature of Enlarged Cervical Glands.**—"Out of over 2,000 cases of phthisis I have only seen enlarged cervical glands in 5, and although one occasionally—but very rarely—sees phthisis pulmonalis follow operation on these glands, it might be explained by direct extension of the deep cervical lymphatic glands to the apex of the lung. How many scores of strong, healthy, vigorous children and adults do we see who have suffered from tuberculous glands in the neck with never a symptom in after-life. Surely these people cannot be classed as tuberculous; they have suffered from a mild infection of tubercle bacilli, which was in all probability bovine in origin and absorbed from milk.

"I was particularly impressed when attached to the Dundee Royal Infirmary with the number of strong, healthy, vigorous children from the country districts in Forfarshire who were brought to the hospital suffering from enlarged glands and strumous joints. In many cases general constitutional treatment, with change of air—for change of air means change of cow—produces a cure, or, if necessary, remove the glands or diseased joint, and the child becomes fat, and makes a perfect recovery.

"The most reasonable theory is that scrofulous glands in the neck are produced by the absorption of tubercle bacilli in milk through the tonsils and pharynx, and is, as a rule, a purely local affection. This view is supported by feeding experiments on animals. If pigs are fed on tuberculous milk they invariably develop enlarged tuberculous glands of the neck and throat which on inoculation produce bovine tuberculosis in cattle, and tuberculous lymphatic glands from the human when injected into calves have produced a general tuberculous infection. This is strong presumptive evidence of their being bovine in origin.

"If this view is correct it would help to explain the occurrence of acute general tuberculosis occurring in those suffering from an unhealed focus, such as a gland, a strumous joint, or a psoas abscess, for we are all aware of the danger of operating on a caries of the spine, a tuberculous bone lesion, or removal of glands, lest a general blood infection should follow. If we observe closely this acute general tuberculosis we find it closely resembles that seen in cattle, affecting chiefly the serous membranes and the lungs, a condition which rarely accompanies phthisis pulmonalis.

**Tuberculous Meningitis.**—"It is often a matter of perplexity to the doctor to explain the onset in a previously healthy child of an attack of tuberculous meningitis. Sometimes it is confined to the brain, at others it is part of a general infection. Perhaps it is a bovine tuberculosis, as we have all seen necropsies where

there has been no other discoverable evidence of tubercle. There is also much evidence to suggest that acute miliary tuberculosis is also bovine in origin. I have mentioned a few points briefly with the object of having the opinions of others on this difficult and absorbing problem, and I conclude by expressing the opinion, based almost exclusively on clinical and pathological evidence, that human and bovine tuberculosis are distinct varieties of disease, as shown by Professor Koch, but that the human body is susceptible to both, and especially to bovine tuberculosis in the early periods of life.

"The two diseases are so rarely seen together in the human that there seems to be some ground for presuming that they are antagonistic to each other, and that bovine tuberculosis may possibly confer an immunity against human tuberculosis. If this opinion should prove correct, I venture to submit that it would reconcile the conflicting opinions which have been so frequently expressed during the last two years on this most terrible of all diseases."

W. Arbuthnot Lane said: "I should like to insist on the importance of recognizing that either local injury or disease predisposes to infection. The glandular enlargement, so often seen in children, is much too readily assumed to be tuberculous. Many other causes give rise to it."

**Koch's Announcement.**—Dr. Douglas A. Reid said: "Until the meeting of the British Congress on Tuberculosis in 1901 it was an accepted creed that bovine and human tuberculosis were one and the same disease and that it could be transmitted through meat and milk from cattle to the human subject.

"Then came the bomb-shell of Professor Koch, exploded with great suddenness and with far-reaching effect throughout the civilized, and particularly the medical, world. The eminent professor in starting a new creed used words that will be memorable throughout the ages. 'I should estimate the extent of infection by the milk and flesh of tuberculous cattle and the butter made of their milk as hardly greater than that of hereditary transmission and I therefore do not deem it advisable to take any measures against it.' Inasmuch as the theory of hereditary transmission has now been practically abandoned this must be read to mean that bovine tuberculosis cannot be transmitted to man. Dr. Nathan Raw has advanced a third creed, which somewhat adds to our difficulties in coming to a conclusion in the matter. If there is a 'variety of bovine tuberculosis that can be conveyed by milk from tuberculous cattle' then we are right, and the Government is right and the National Association is right in warning the public to avoid tuberculous meat and milk, and Professor Koch is wrong in advising a contrary procedure.

**Tuberculosis Rare in India.**—"But while experiments and investigations are going on, who can say positively where truth can be found? What has become of the French doctor who inoculated himself with bovine tubercle? It is not my intention to occupy your time with opinions of my own on this subject, but, by the courtesy of Dr. Crombie, I am enabled to contribute some facts and statistics connected with India that may be of value when we come to weigh the evidence for and against the different views that have been advanced. Dr. Crombie submitted a report to the Secretary of State for India on the Congress on Tuberculosis at Berlin in 1899, which was published in the report of the Sanitary Commissioner with the Government of India for that year. This publication is not easily available, and Dr. Crombie has very kindly obtained for me a copy of that part of his report bearing upon tuberculosis in India. It must be borne in mind that a large number of persons die in India without any medical attendance whatever, and therefore in some parts only of the country can statistics be obtained, and one part is in the Northwest Provinces. Here during the year 1897 the cause of death was verified in 15,116 cases by means of the medical staff and a professional agency which voluntarily supplied the required information. Of these 15,116 deaths, 40 only were from tubercle of the lung—6 children and 34 over the age of sixteen years. There were no deaths among children from tabes mesenterica or tuberculous meningitis. The 6 children who died were all under eighteen months. The experience of all medical men in India is that in contrast with that of Europe diseases of the chest, and phthisis among them, take quite a subordinate place in the sickness and mortality of India, and that the tuberculous diseases of children are exceedingly rare among the civil population. Dr. Crombie further reports: 'With regard to tuberculous diseases among children, all authorities are unanimous as to their rarity. Taking strumous enlargement of the cervical glands as the commonest and most obvious form of tuberculous infection in children, Chevers says that he never saw a case in a native of the plains of India.' And other authorities confirm this. Tuberculous meningitis is, however, met with in India, but less frequently than in Europe. Tabes mesenterica is certainly very rare among the civil population. Chevers says that he never admitted a case to hospital. Morehead does not mention it as occurring in the large Byculla schools at Bombay, neither do Webb and Fayrer as regards the Calcutta schools, and the contemporary accounts of the health of the children (mostly Indo-Britons) at the Madras orphan asylums are silent with regard to it. It was at one time, however, apparently very prevalent among the children of European soldiers serving in India. From 1880 to 1883 inclusive there were 162 admissions and 86 deaths from tabes mesenterica among European children in India, while only 3 prisoners and 5 native soldiers were so affected. In 1896 there were no cases in the native army or gaols of India.

"Tuberculous disease of the hip-joint is exceedingly rare. Dr. Crombie never saw a case, nor have any of the medical officers whom he has questioned. From the very interesting statistics in Dr. Crombie's report it is not clear that the great immunity of residents in India, both native and European, so conspicuous in childhood, is extended in an equal degree to adults, at least as regards the conditions under which our soldiers and prisoners live.

"The causes of lesser prevalence of tuberculosis in India are given by Dr. Crombie as follows: (1) The comparative infrequency of bovine tuberculosis in India. (2) The native habit of boiling all milk before using it. No native of India knowingly drinks a drop of unboiled milk. (3) The exclusion of beef from the food of a large proportion of the native population. To the Hindu it is an abomination. Stall-fed beef is unknown in India, even in the large towns. (4) The flesh of the goat is almost exclusively used by Mohammedans, that of the sheep by Europeans. The goat is one of the animals most 'refractory' to tuberculosis. Goat's milk is also much used by the natives. (5) The open-air occupation of the natives. (6) Abstinence from alcohol. (7) The native of India converts all his butter into "ghi" by a process of boiling and skimming, which must destroy any tubercle bacilli it may contain. The European in India eats raw butter. (8) Children in India have this additional advantage over European children (in India) that their mothers al-

most without exception suckle them until they are two or three years old. (9) The comparative infrequency of the diseases which seem most frequently to predispose to tuberculosis—namely, measles, scarlatina, and whooping-cough—which, when they do occur, are milder than in Europe (Ewart).

"The inference to be drawn from the preceding facts is that where the flesh and milk of bovine animals is not much used by the people, and especially where cow's milk, except in a boiled state, is not used for the feeding of children, tuberculous diseases are extremely rare, and that this affords evidence against Professor Koch's contention.

"On the other hand, we have to face the statement, which I suppose we must accept as a fact, that a very large number of milch cows are tuberculous and that the number so affected is increasing. As an increasing number of British mothers refuse to suckle their children we ought to find more tabes mesenterica and tuberculous peritonitis among the children. Dr. Raw says it is so, and this I was not certain about, having no reliable statistics to guide me."

**Contamination of Milk in the Home.**—Dr. John Mackenzie said: "I cannot accept that all the tuberculosis found in children is due to milk infection. The children of the poor are often breast-fed. The mothers believe that while they suckle their children they will not conceive again. The milk is kept in the homes of the poor under conditions that greatly encourage tuberculous infection, if it should be otherwise present in the house. Tuberculous meningitis I have often observed to be due to disease of the middle ear. The enlargement of cervical glands may be due to scarlet fever, diphtheria, and septic sore throat. Hence we must not rush to the conclusion that all large cervical glands are tuberculous."

**Possibility of Primary Abdominal Infection.**—Dr. Theodore Fisher said: "I think Dr. Nathan Raw takes too extreme a view. I do not, of course, deny the possibility of primary abdominal infection, or that such infection is sometimes of bovine origin, but that infection through the respiratory tract is far in excess of that through the alimentary tract my own experience seems to leave no shadow of doubt. Statistics may be quoted of the relative frequency of infection of the bronchial and mesenteric glands from Germany, France, and America, which present the matter in a different light from that given by Dr. Raw. In my experience the primary or only focus of infection is, in the great majority of instances, in the bronchial glands. Extension of infection from the mesenteric to the bronchial gland must be extremely rare. I can mention cases showing that tuberculosis peritonitis and other forms of acute or subacute tuberculosis of abdominal organs may occur where the only caseous focus is in a single bronchial gland hidden within one lung."

Dr. W. Langford Symes said: "I wish to ask Dr. Raw what he actually means by tabes mesenterica. Dr. Raw quotes 273 cases of tabes. There are three forms of abdominal tuberculosis usually seen—namely: (1) Tuberculous peritonitis, of two or three kinds; (2) tuberculous ulceration of the bowels; (3) tabes mesenterica where the glands alone are affected. This latter is in reality the rarest of all kinds, and the use of this term frequently gives rise to misunderstanding."

**Double Infection.**—Dr. Edmund Cautley said: "In one point I agree with Dr. Nathan Raw, namely, that probably the bovine bacillus gives rise to a different form of tuberculosis to that produced by the human bacillus, and that children are subject to both kinds of infection. I differ from him in regarding infection by the bovine bacillus as of comparatively rare occurrence. It is with the greatest regret that I hear Dr. Raw perpetuating that unfortunate name 'tabes mesenterica.' It has led to endless confusion, and, on the grounds of scientific precision, should be omitted from the nomenclature of the tuberculous affections. I am still more astonished to hear him quoting Sir Richard Thorne-Thorne's statistics of tabes mesenterica in support of his views. Time after time it has been pointed out that these statistics are absolutely valueless. They were taken from the Registrar-General's reports, and it is well known that in those reports all cases certified as deaths from 'consumptive bowels' are included under the heading of tabes mesenterica. This is absolutely misleading, for almost all cases so certified are nothing more nor less than cases of marasmus due to diarrhea and vomiting, from unsuitable feeding, and ending in death. I am not inclined to accept the statement of veterinary surgeons that about 30 per cent. of English cows are tuberculous. Such a statement may be true of highly-bred pedigree stock and of old milch cows kept under unsuitable conditions, and yet be absolutely inaccurate of younger cows kept in healthy country surroundings. Even accepting it as true, the result is probably based on the reaction to tuberculin, and does not indicate that the milk is likely to be infective. The fact that many children get a mild infection and recover is to my mind an argument of no value in favor of the views of Dr. Raw. The liability to infection by the human bacillus is enormous in the conditions under which the very poor live, and the milk may be infected by the human as readily as by the bovine bacillus. From the experience of a large hospital practice for many years I have derived the impression that tuberculous meningitis diminishes in frequency in proportion to the increased use of cow's milk in infant feeding. Certainly the proportion of such cases has very much decreased in my experience under such conditions. I regard condensed milk as a potent factor in the etiology of tuberculous affections, by lowering the vitality of the child, and rendering it more susceptible to infection by the human bacillus. As to infection via the alimentary tract in opposition to infection through the pulmonary system, I should like to quote the result of 27 necropsies on cases of tuberculous meningitis. In 25 instances the state of the mediastinal and mesenteric glands was noted, and in no less than 23 were one or more of the mediastinal glands caseous. In 4 out of these 23 the mesenteric glands were also caseous, but in none were they the only ones involved. On the whole, it seems to me that up to the present we have no justifiable grounds for concluding that tuberculous milk is a serious source of infection."

**Primary Infection of Glands.**—Dr. George Carpenter said: "Certain cases of tuberculosis are, in my opinion, primarily abdominal. If infection of the lungs takes place in these cases, it is probably secondary, and by way of the thoracic duct. Other channels of ingress are, however, much more usual avenues of infection. In a case of enteric fever with an intestinal ulcer and enlarged mesenteric glands, I found both tubercle and typhoid bacilli in the glands. This proves conclusively that primary infection of the glands can occur. Dr. Raw has not called attention to a well-known occurrence in these cases of a sound mucous membrane with advanced caseous disease of the mesenteric glands. I object to the loose term tabes mesenterica, a nomenclature which should be abandoned. I have in a large experience only seen two cases of glandular disease which could be fairly called tabes mesenterica. The common clinical state is a mixed condition of tuberculous peritonitis, tuberculous ulcers, and caseous mesenteric glands, which can be detected as fixed abdominal

lumps. I should like Dr. Raw to say what he really means to convey by the term tabes mesenterica. I think that many cases of dyspepsia in infants and young children are unwarrantably described as cases of tabes mesenterica. Are Dr. Raw's experiences clinical or pathological? I call attention to the importance of making a combined rectal and abdominal examination in doubtful cases. It is possible in this way to determine the presence of tuberculous peritonitis. Dr. Raw has spoken of abdominal section in these cases. I consider abdominal section unjustifiable, and all that is necessary in some cases of ascites when there is considerable distention by fluid is the simple operation of paracentesis abdominis, preferably by Southey's trocar and canula. Abdominal section should only be undertaken when there is pus in the abdomen or for the relief of intestinal obstruction. Dr. Raw has stated that he has never seen a case of abdominal tuberculosis which has not been fed on cow's milk. My experience is somewhat different, as I have met with two primary cases in breast-fed infants. In one of them the appearance was that of simple chronic peritonitis. The false membrane could be stripped off the intestines, leaving a polished surface, and it was not until a microscopical examination was made of this membrane that its tuberculous nature was recognized—it was crowded with tubercle bacilli."

**Glandular Invasion Secondary to Trauma.**— Mr. Adam Eccles said: "I wish to emphasize the remark which fell from the President that, from a surgical point of view, there seems to be much evidence that there is a lesion prior to the infection by the tubercle bacillus. I think that there might be direct infection through the blood stream, without involvement of the cervical glands, of both meninges and of joints. So many children suffer from lesions of the tonsils and nasopharynx that it would seem possible, even probable, that bacilli in milk may be arrested and imprisoned here, and become directly absorbed. In tuberculous peritonitis, if there is no secondary infection, recovery would seem to be the rule, and therefore the question of a primary tuberculosis of the abdomen is important from a point of view of prognosis."

Dr. Nathan Raw, in closing, thanked the members of the Section for their criticism of the points raised in the paper, and read a letter from Professor Madden (Cairo) supporting his view that children in Egypt were not often attacked with tuberculous glands or abdominal tubercle owing to the general custom in Egypt of suckling the children up to the age of two years. He was strongly of opinion that tubercle spread from the abdomen to the lungs in children a great deal more frequently than vice versa. He concluded by affirming the view that human and bovine tuberculosis were different species of tuberculosis, and that the child was more susceptible to bovine than human infection, and that the general mode of infection was by the ingestion of tuberculous cow's milk.

## BOOK REVIEW.

Findley's Gynecological Diagnosis. The Diagnosis of Diseases of Women. A Treatise for Students and Practitioners. By Palmer Findley, M.D., Instructor in Obstetrics and Gynecology in Rush Medical College, in affiliation with the University of Chicago. In one octavo volume of 494 pages, richly illustrated with 210 engravings and 45 full-page plates in colors and monochrome. Cloth, $4.50, net; leather, $5.50, net. Lea Brothers & Co., Philadelphia and New York.

At a time when prominent men are talking of the "passing of the specialty," and the cry is raised in some quarters that Gynecology has no more worlds to conquer, the appearance of a volume devoted exclusively to *gynecological diagnosis* is an evidence of faith, in at least some quarters, that gynecology still retains a goodly modicum of reserve force and staying qualities. This confidence is not misplaced. There is a future for the specialty as well as a lustrous past. It will consist in elaborating technic and in perfecting diagnosis. In the latter particular the book before us is a step in the right direction, and worthy of all commendation. If the author has made any mistake it is in the endeavor to cover too much ground, rather than elaborate to the last detail, and spend his time upon, conditions particularly difficult of diagnosis. The author's directions for digital examination of the internal genitals is a case in point, especially the combined or bimanual method. The method is extolled as "the most valuable of all physical explorations of the pelvis," and considerable time is expended in telling what can and what cannot be done, but it is doubtful if anyone, by reading this chapter, would gain much insight into how, practically, to apply the method. The picture on page 59, purporting to illustrate the method, is altogether faulty. The table is too high and the operator too far away from the patient. Working at arm's length and at so high a reach it is impossible to make efficient pressure either in the vagina or on the abdomen; it is no wonder that the list of things that cannot be done is long. The same criticism, in a general way, will apply to the chapter on displacements of the uterus. The illustrations of the conditions are clear and instructive, but the explicit directions for their detection are not so lucid.

As the author truly says: "The recognition of the pathology of the pelvic organs in large measure constitutes a diagnosis." Acting upon this principle he has incorporated a thorough discussion of the morbid anatomy, both macroscopic and microscopic, and added valuable suggestions on the clinical indications. Special stress has been laid upon the microscopic findings in the various lesions, emphasizing the fact that "without the microscope a diagnosis is not always possible."

The chapter on ectopic pregnancy elaborates the subject well; it is beautifully illustrated, is concise and clear. The diagnosis of pregnancy, especially in its early stages, and abortion, is most apropos. In Chapters XVIII and XIX may be found a very instructive discussion of that rare condition of hydatiform mole and chorio-epithelioma malignum, more commonly called deciduoma malignum. In the discussion of cancer of the uterus the author follows closely Cullen's masterful presentation of that subject. The chapter points out emphatically the importance of early diagnosis—prompt and thorough examination, both macroscopic and microscopic, in all cases presenting the least suspicion of malignant tendencies—and tells how to do it. The diagnosis and pathology of diseases of the ovaries are fully presented—this is one of the best chapters—and the book closes with a brief treatise on the urinary apparatus, the urethra, bladder, ureters, and kidneys.

The book, as a whole, is an agreeable résumé of what is presented in the various text-books on gynecology. There is nothing new presented and nothing impressive or remarkable in the manner of its presentation. But some valuable hints are dropped here and there; the index is full and complete, and altogether, the work affords a reliable and convenient reference book covering the entire field of gynecological diagnosis.

The volume has a most attractive appearance, is generously illustrated, and does credit to the publishing house from which it emanates.

# THE MEDICAL NEWS.

## ORIGINAL ARTICLES.

### CONCERNING SOME POINTS IN THE TREATMENT OF TYPHOID FEVER.*

BY GLENTWORTH R. BUTLER, A.M., M.D.,
OF BROOKLYN, N. Y.

WITH regard to the treatment of typhoid fever, I wish to speak concerning diet, the use of cold and the employment of drugs. The following statements are for the most part based simply on personal opinion and experience:

*Diet.*—Notwithstanding severe criticism, milk remains the best article for the basis of a typhoid fever diet. It has been condemned as an excellent culture medium for the bacillus, scored because of forming indigestible curds, and accused of being responsible for fermentation and excessive tympanites. All of these consequences and faults can undoubtedly be attributed in varying measure to the exclusive milk diet, but the acknowledgement simply emphasizes the fact that no one article of food is at all times and under all circumstances the best and most suitable for a patient with typhoid fever. Many patients have gone smoothly and uneventfully through the whole course of the disease without taking a particle of nourishment other than milk, but the sameness of the diet becomes excessively monotonous and at times revolting. On the other hand, there are some persons who, I am satisfied, have an idiosyncracy for milk and will vomit it, or, if it is retained, will digest it with distress and difficulty.

By a gradual process of development I have come to include the following articles in the routine typhoid fever diet: The administration of milk may be much varied. Thus we may give milk, milk and mineral waters, buttermilk, koumyss, oyster and clam soup made with milk, milk made into soup by salting, peppering, and heating with a little butter, hot milk flavored with a little strong, black coffee, or cold with a small quantity of whisky, brandy, or rum, or a sprinkle of red pepper. The latter is liked particularly by patients who are in the habit of drinking spirits. It is understood that the stools are daily scrutinized for undigested curds. If such appear the milk may either be stopped, or diluted one-half with water, plain or mineral, or peptonized by the cold process. In every case, if the patient is accustomed to drinking coffee, tea (hot or iced) or cocoa, these are allowed once or twice daily. With many persons the prohibition of these accustomed beverages is a serious, and, I believe, an unnecessary and harmful deprivation. In all cases lemonade, orange juice or grape juice are not only allowed, but their use encouraged, unless there is a troublesome diarrhea. Mutton, beef, and chicken broths, bouillon, consommé, or other clear soups are also given in moderation, unless, as with fruit juices, the bowels are moving too freely. Albumen water, the whites of eggs, mixed with an equal or somewhat greater amount of cold water, strained through a cloth, acidulated with lemon juice, and flavored or not with spirits, is often useful. The white of the egg or the whole egg may be beaten with milk and employed, a little sparingly perhaps. Barley gruel, thin and well strained, is a good food and relished by some, especially if well salted. Plain ice-cream, water ices and jellies are, as a rule, unobjectionable. Lactose, sugar of milk, is a valuable force producer, and as it is both soluble and wellnigh tasteless, can be given to great advantage one or two, or more, ounces daily, dissolved in milk or water.

The foregoing list affords possibilities, not only in degrees of digestibility and nutritive value, but in variety, and the latter is of no small importance, except in those patients who are dull and delirious. The physician at each visit should carefully arrange the hours of administration, the amounts, the kinds, and the sequences of the nourishment to be given, writing it out in detail, if necessary. There is a distinctly better morale when the invalid's palate is consulted, even though the sense of taste be measurably blunted. It is doubtless often the case that in our anxiety to maintain the nutrition of the patient at its highest point we give more food than can be digested or utilized. A persistent feeling of gastric discomfort, or overfulness, nausea, tympanites, or, if the diet contains milk, the appearance of curds in the stools, should be the signal for alterations in the schedule of nourishment designed to correct the symptoms of imperfect digestion. The milk may be cut out altogether or lessened in amount, or diluted, or peptonized, or other fluid foods may be temporarily diminished in quantity or frequency. Cases have been known to do very well on water alone for several days.

Water should be given just as regularly as food. This, to me, is a matter of great importance, because it is an effectual and indispensable means for keeping the total daily output of urine not only up to, but above, the normal daily average. It has been shown that the kidneys are the most efficient excretors of typhoid toxins. The experiments of Ingelraus and Dehon on the toxicity of the urine in three groups of cases of typhoid fever treated respectively by warm baths, cold baths, and the ingestion of large amounts of water, are of much interest in this connection. The toxicity of the urine was least with the warm baths, and greatest in patients who drank large

*A portion of a paper read before the Brooklyn Medical Society.

quantities of water, proving very satisfactorily that elimination of toxins was better accomplished by increasing the excretion of urine than by cold or warm baths. Water should, therefore, be given systematically, 6 to 12 ounces, or even more, if it does not incommode the patient, every two hours. Except in the mildest cases it is also desirable to give by rectum, once or twice daily, half a pint to a pint of warm normal saline solution.

With regard to the use of solid food, I believe most firmly that it should not be allowed until three days of normal temperature have elapsed, and in particular that no meat should be given until ten days of freedom from fever have passed. No one will ever regret the observance of this rule; many have bitterly mourned its non-observance. I am very well aware of the good authority for the giving of solid food, not only as soon as the patient desires it, but even during the course of the fever. Nevertheless, I have seen too many recrudescences of fever, particularly after the too early taking of meat, to be shaken in this opinion. Not without cause did the term *febris carnis* come into being; moreover, when one has seen an autopsy or two where nothing intervened between the patient and a perforation but an almost transparent film of peritoneum forming the floor of a typhoid ulcer, he is apt to meditate upon the not unlikely consequences of the passage of a tiny spicule of bone from a mutton chop, or a sharp seed case from an apple, or perhaps a solid piece of imperfectly cooked, poorly masticated or ill-digested vegetable or meat.

After the third day of normal temperature milk toast or crackers softened in milk, soft boiled or poached eggs, boiled rice or rice pudding thoroughly cooked, jellies, ice cream, oysters, baked potato, in general a farinaceous and fluid diet, may be allowed. After the tenth day, chicken, beef, steak and chop may be added.

*Hydrotherapy.*—So far as personal observation may be trusted, it would appear that the routine use of the cold tub in typhoid fever is not so common now with many good men as it was a few years ago. This is so not alone from the fact that in private practice the method is so troublesome and expensive as to be practically unavailable in the majority of cases. Even in hospitals, with the ready outfit and ample supply of trained attendants, cold tubbing is by no means so frequently employed, so that this change in the therapeutics of typhoid fever, while sufficiently marked to be noticeable in papers and discussions, is not due simply to the practical difficulties of cold bathing. The mild cases, with fever not exceeding 102.5° F., do not require it; a majority of the severer cases get along not only very well, but distinctly better with gentler means; and in a measurable proportion of patients tubbed, the cold baths have to be omitted because of a lack of proper reaction, even though the technic of the bath is as perfect as the most minute attention to details of the best practice can make it. Personally for the robust, strong-hearted, full-blooded type of man or woman I still employ it from the beginning, when practicable; for others it is best to begin, and continue, if the results are satisfactory, with less heroic hydriatic procedures, which involve the minimum of physical and mental disturbance to the patient, reserving the right to shift to the cold tubbing if the end and aim of the use of cold water is not attained by the less disagreeable measures.

It should be distinctly understood that the reduction of temperature is not the main object of the hydriatic treatment in typhoid fever. On the contrary, lowering of the fever, although desirable and often a good gauge of the effect of the treatment, is of quite secondary importance to the tonic and stimulating effect of cold with friction, upon the heart and arteries, the respiratory tract, and the functions of the nervous system, as well as the increase of the urinary excretion and its toxicity. Cold with friction of the surface should be emphasized, as one without the other is of comparatively slight service in attaining the desired results, viz., to counteract the effect of the toxins upon the nervous system and increase their elimination and destruction.

For the application of cold the following methods can be commended. The details are important:

1. Cold Mitten Rub.—Required: A rather rough bath mitten, a bath thermometer, a vessel holding a gallon of water, reduced to a prescribed temperature by ice, a rubber sheet, a blanket, a linen or Turkish sheet, and a couple of towels. The rubber sheet covered by the blanket is placed under the patient, the body clothing removed, and the sheet placed over him. The face, head and neck are wet with cold water, or, in women, a wet napkin is placed over the face. The front of the thorax is then uncovered and the nurse, dipping her mittened hand into the water, rubs the surface vigorously until it is well reddened, frequently redipping the mitten in the water. When a good reaction of the skin is secured, the thorax is quickly rubbed dry with a towel. The remainder of the body is similarly treated, in order, right arm, left arm, anterior aspect of legs, then, the patient having been turned upon his face, the back, and posterior aspect of the legs. The mitten rub may be repeated at intervals of three to six hours when the fever reaches or exceeds 102.5° F.

For the first rub the temperature of the water may be 85° F., for the second 80° F., for the third 75° F. Usually 65° F. is the lowest temperature required, but the water may be reduced to 45° or 40° F. if greater stimulation is necessary. The cold mitten rub has given tonic effects quite as good as those of the cold tub with a very desirable minimum of disturbance to the patient. It has a very different action from ordinary sponging, in which the surface of the body is merely moistened with cold water, applied by a soft cloth, without friction.

2. Towel Bath of Baruch: For the employment of the towel bath, the bed is prepared as for

the mitten rub. Required are two linen towels, a large cup, a sponge, a basin of water at 85° F. and another at 70° F. The patient is turned upon his abdomen, a towel having been dipped in the 85° F. water, is, without wringing, laid smoothly over the entire back, gluteal regions and thighs, using both towels if one is not large enough. With the cup, the water at 70° F. is poured over a part of the back, *e.g.*, the upper left, and this part rubbed vigorously with the flat hand until the surface is felt to be warm, and another cup of water poured on followed by more rubbing. This may be repeated three times unless the part does not become warm. The remaining parts of the back and the thighs are gone over in a similar manner and carefully dried. The patient is then turned on his back and the procedure repeated over the anterior portion of the body and thighs. From time to time, as required, the water which has flowed upon the blanket is sopped up and removed with the sponge. According to indications the towel water may be reduced to 60° F. and the cup water to 50° F.

3. The Ice Rub: The ice rub is distinctly more vigorous in its action and like the cold tub requires discrimination in using. The bed having been prepared with the rubber sheet and blanket, the patient may either be wrapped in a sheet dipped in 85° F. water, or the wet towels may be used as in the towel rub. But instead of pouring water on, a part of the surface is rubbed with a flat, smooth piece of ice, held in a wash-cloth, followed by friction with the flat hand until it warms up. This is to be repeated until the part remains cool. The whole body is successively gone over in this manner, and carefully dried.

The first method, the cold mitten rub, will suffice for nearly all cases. If a more refrigerant and stimulatory procedure seems necessary, the towel bath may be used, and, finally, if required, the ice rub. The nurse should promptly stop the giving of any one of these hydriatic measures if the patient's teeth begin to chatter. Complaints of simple chilliness may be disregarded.

During the intervals between the cold rubbings, a wet compress to the abdomen is highly recommended by hydrotherapeutists, although I have seldom employed it. It is applied by cutting three thicknesses of old linen to fit the front of the body from the lower end of the sternum to the pubis, and wide enough to lap over the sides of the abdomen. This compress is dipped in water at 65° F., wrung out so as to be moist without dripping, and smoothly applied, the gown having been rolled up out of the way. The compress is now covered by a flannel binder, of a size sufficient to pass completely around the body, and to overlap the wet compress by an inch or more, above and below. It may be secured by safety pins in the ordinary manner. It is to be renewed every hour.

*Prophylaxis Against Relapses.*—Owing to some favorable statistical reports, for the most part from German sources, it is extremely desirable to employ certain preventive measures against relapses. These measures are based upon the reasonable ground that reinfection may occur from the outside, especially from the hands of the patient. In addition to cleansing the hands and arms with a disinfectant solution, the finger nails should be cut short, and the hands scrubbed twice daily, with soap and water, followed by two or three minute immersion in a warm 1-1,000 bichloride solution. In a limited number of personal cases, no relapses have occurred when this has been done. In fly-time sedulous care should be taken to keep flies from the patient by bed and window screens, and to keep food and utensils covered to avoid their contamination by these pestiferous insects. This precaution is in the interest, not only of the patient, but as well of the attendants and residents in the building.

*Medicinal Treatment.*—It is probable that most cases of typhoid fever are overmedicated. It is simply appalling at times, even in hospital service, to see the list of remedies grow in bulk, by almost imperceptible additions at each visit of the physician, and it may require considerable self-control not to yield to the natural impulse which urges one to relieve or to meet every indication, whether important or not, which may arise. This piling up of remedies is extremely apt to disorder the stomach and to cause certain incidental untoward and undesirable by-effects. Many cases of typhoid fever do best with little or no medication, but at the same time I have no sympathy with therapeutic nihilism, and in the face of gradual cardiac failure, pneumonic complications, intestinal hemorrhage or similar serious developments, no one need hesitate to employ heroic medication if it seems necessary. There is neither reason nor humanity in allowing a case to progress steadily toward a lethal ending without employing medicaments which have proved indubitably life-saving in many instances.

There are but two points in medicinal treatment of which I wish to speak—intestinal antisepsis and the checking of intestinal hemorrhage.

Few well-informed men now expect to accomplish anything in aborting typhoid fever by destroying the bacillus in the intestines. The proved presence of the germs in the blood and internal organs forbid any such anticipations. Nevertheless I am satisfied from clinical experience that the ordinary putrefactive and fermentative changes which take place in the intestinal tube can be favorably modified by antiseptics, and that in consequence excessive tympanites, always an event to be deplored and dreaded, is of much less common occurrence when suitable remedies are systematically employed. Among eligible intestinal antiseptics are salol, guiacol carbonate, creosote carbonate, zinc or sodium sulphocarbonate, bismuth, and turpentine. These may be given in moderate doses at intervals of four to six hours. An initial dose of calomel is desirable, and during the course of the disease, especially when constipation exists and the stools are fetid, small doses of calomel 1-5 to 3-5 gr. with 1-10 to 3-10 gr. of ipecac and a little sodium bicarbonate

have often proved of good service in lowering temperature and relieving general and gastro-intestinal discomfort. As a rule daily enemata are sufficient.

For the medical treatment of intestinal hemorrhage three remedies have proved to be of much value. The first two, which act by increasing the coagulability of the blood, are calcium chloride and gelatin; the third, an arterial constrictor, is the powdered suprarenal or its active principle, adrenalin. A pint or more of a 10-per-cent. solution of gelatin may be given in the twenty-four hours; 20 to 30 grains of calcium chloride every two to four hours; and 5 or more grains of the desiccated supranenal every four hours, up to half a dram in twenty-four hours. The results have been sufficiently encouraging in personal cases to make the administration of these remedies a routine measure, in preference to the opium, ergot and lead of former treatment. The use of moderate doses of opium or its alkaloids is always advisable in order to quiet the restlessness and excitement usually attending internal hemorrhage, and to sustain and regulate the action of the heart.

---

## NOTE ON TYPHOID FEVER AND SCARLET FEVER WITH SPECIAL REFERENCE TO THE DIAGNOSTIC VALUE OF BLOOD CULTURES.*†

BY LUDVIG HEKTOEN, M.D.
OF CHICAGO.

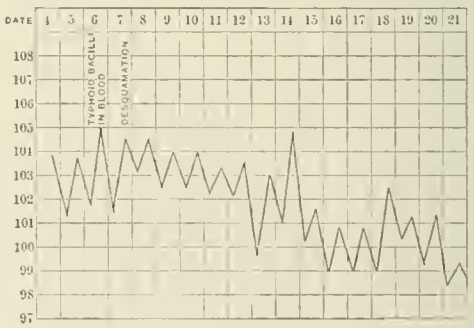
This brief communication is written for the purpose of calling attention to two points, first, the possibility of mistaking typhoid fever for scarlet fever on account of early rash and angina, as well as the possible coincident occurrence of these two diseases in the same person; and, secondly, the value of bacteriological examination of the blood in determining in such cases the existence of typhoid fever.

Recent investigations have shown that in the early stages and during the height of the attack of typhoid and paratyphoid fever the specific bacilli occur in the blood so constantly and in such numbers that they are readily demonstrable by cultural methods. Such appears to be the case also at the beginning of relapses in typhoid fever (Schottmüller, Rüdiger). In many respects this is the most important recent advance in our knowledge of these diseases, and bacteriological examination of the blood according to the modern methods of several inoculations of 1 c.c. or so of blood into many times that quantity of medium constitutes the most valuable diagnostic measure of these fevers at the periods mentioned. Repeatedly have bacilli been demonstrated in the blood many days before the appearance of specific agglutinins.

According to Curschmann‡ the concurrence of scarlet fever and typhoid fever has been described by Taupin, Murchison, Glaser and Eichhorst. In Murchison's and Glaser's cases, scarlet fever seems to have developed in the second or third week of typhoid fever, and Curschmann remarks that most frequently in this association the development of scarlet fever is secondary. In the following case it is reasonable to believe that scarlet fever and typhoid fever developed very nearly at the same time. At all events, the onset, the angina, the rash, the tongue, and the desquamation were quite distinctive of scarlet fever; and the demonstration of typhoid bacilli and of specific agglutinins in the blood as well as the subsequent course of the disease leave no room for doubt as to correctness of the diagnosis of typhoid fever.

*Case I* (No. 185).—Woman, aged twenty-two years; married; housewife; was admitted to Dr. Baum's service in ward No. 26, Cook County Hospital, on October 12, 1902.

The history (Dr. Otradovec) states that she was taken suddenly ill three days before admission with nausea, malaise, headache, pain in the limbs. The throat began to swell, became red, and deglutition was difficult and painful. On the following day a rash appeared on the neck and body, spreading to the limbs and face. The examination at the time of admission showed a diffuse erythematous rash on the neck and body, face and limbs. There was a deep, subcuticular flush with raised points. The tonsils were enlarged and swollen, but without membrane; strawberry tongue. On October 14, cultures of the blood were made and the typhoid bacillus occurred in pure growth. The serum was then strongly agglutinating for typhoid bacilli. On October 15 it is noted that typical scarlatinal desquamation was going on. On October 18 the



Case I.—Temperature Chart.

spleen was palpable; there were numerous raised spots on the abdomen; quite frequent bleeding from the nose; headache persisted; the bowel movements frequent.

Recovery took place after a typical typhoid course, the temperature falling to normal about the twenty-first day.

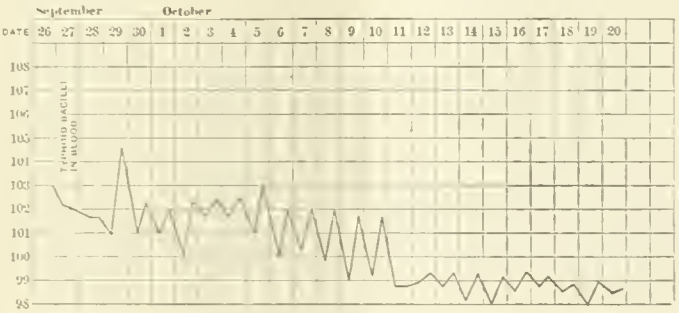
It must be granted that the skeptic might find room for questioning the correctness of the diagnosis of scarlet fever in this case. As stated,

* From the Memorial Institute for Infectious Diseases.
† Presented at the meeting of the Association of American Physicians, May, 1903, Washington, D. C.
‡ Nothnagel's Specielle Pathologie u. Therapie, 1898, III B., I Theil, 303-304.

the onset, the angina, the rash, the tongue, and the desquamation seemed distinctive of scarlet fever, but in the absence of absolutely conclusive evidence, such, for instance, as would be furnished by the demonstration of the etiological agent, one could not successfully disprove the claim that all the symptoms were caused by the typhoid fever. But general desquamation does not seem to occur, at least in the lighter forms of typhoid erythema. In his valuable paper on "Anomalous Eruptions in Typhoid Fever," the late Da Costa* states that the scarlatiniform eruption in typhoid passes away without desquamation. The occurrence of desquamation in this case seems to be, therefore, to support strongly the diagnosis of scarlet fever.

It may have been cases of this kind that gave rise to the following description by Thomas of "scarlatina with a course similar to typhoid fever," which I give word for word with Von Jürgensen's comments, as translated in the American edition of the latter's work on scarlet fever in Nothnagel's system:

"By no means seldom occurs still another form of the disease, characterized by slight or moderate



CASE II.—Temperature Chart.

localizations, and by disproportionately severe and very long-drawn-out fever. The latter feature, together with the considerable intensity of the pyrexia, warrants the term 'scarlatina, with a course similar to typhoid fever.'

"Evidently in this form the fever is of major, and the local affection of minor, importance, although at times nothing more than a protracted local disturbance appears to cause the continuation of the fever into the fourth week and longer.

"The *eruption* in this form of scarlatina appears usually after a hyperpyrexia of several days' duration, which follows a sudden initial fever. It is often unusually slight; otherwise it develops according to rule. The *angina* is second in importance of the local affections, and is also frequently of no consequence. It is, as rule, present in advance of the exanthema. Notwithstanding these facts, *brain symptoms and fever*, especially in the beginning of the disease, are not infrequently quite marked; the expression is vacant, thirst severe, and the tongue tends to dryness, yet clearing itself in a characteristic manner. Some cough may be present, and the skin, which, after the fading of the exanthema has desquamated as usual, remains dry and hot. Later the patient is apathetic, and in addition to some slight affection of the organs of hearing, is usually deaf. The spleen swells somewhat, *hypostasis may occur in the lungs*, and the bowel movements are of the nature of a diarrhea. As a rule, no local affection other than a moderate enlargement of the cervical lymphatic glands is perceptible in connection with the remittent fever of weeks' duration."

Von Jürgensen adds: "Nephritis may appear in the third week, and, according to Thomas, determines, when present, the character of the fever."

At the autopsies of the subjects dying in the latter periods of the disease one notes, it is stated, besides the usual involvement of the pharynx, the lymph glands, the skin, and perhaps also the kidneys, "hyperemia of the brain, slight turbidity of the meninges, catarrh of the air-passages and pulmonary hypostasis, transudations into the serous cavities, the liver and spleen full of blood and often swollen, marked floccular involvement of the intestinal tract, and infiltration of its mesenteric lymph glands; sometimes also Peyer's patches are swollen in a manner rather similar to typhoid fever. It is by no means certain that in these cases there is a real complication with enteric fever."

The last remark by von Jürgensen, it would seem, probably does not state the case correctly—it may well be that in some at least of these cases there is a real complication with typhoid fever.

Jochmann* reports a secondary infection with a paratyphoid bacillus in a girl, aged seven years, with undoubted scarlet fever, ending in death on the sixteenth day. Cultures from the blood on the fifteenth day gave a few colonies of streptococci and numerous colonies of paratyphoid bacilli. This result was obtained again after death. There were no special intestinal lesions. In this case there seems to be little or no reason to doubt the diagnosis of scarlet fever—the onset was sudden with vomiting and tonsillitis followed by a pronounced eruption, marked enlargement of the cervical glands, and on the ninth day desquamation.

In the two other cases that I report are prob-

* Transactions American Association of Physicians, 1899, XIV, 89-98.

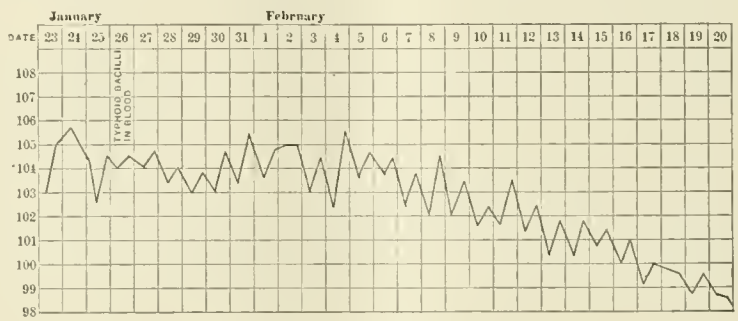
* Centralbl. f. Bakt., Referate, 1903, XXXIII, 8-9.

ably instances of early angina and erythema in typhoid fever.

*Case II* (175).—E. G., single woman, aged twenty-six years, suffered from headache and backache for three or four days, feeling now chilly and then again warm. On the fifth day she remained in bed; about this time she noticed a distinct rash, and there was pain in the throat. With this history she was brought to the Hospital of the Memorial Institute for Infectious Diseases and admitted by the interne as a case of scarlet fever. At the time of admission there was a faint rash on the chest. The cultures of the blood showed pure growths of the typhoid bacillus, which was agglutinated by the patient's serum. This serum also agglutinated in high dilution stock cultures of typhoid bacillus. The patient was transferred to the Presbyterian Hospital and passed through an uncomplicated attack of typhoid fever of moderate severity, ending in recovery. *There was no desquamation.*

*Case III* (238).—J. E., trained nurse, aged twenty-seven years; entered ward 26, Cook County Hospital, Jan. 23, 1902, with diagnosis of scarlet fever. According to the history (Dr. Snyder), the illness began rather suddenly, although the patient had not been feeling wholly well for some time before, becoming easily tired and not having as good an appetite as formerly. This she traced to her being on night duty. The actual onset of the attack is described as marked by headache, backache, and prostration. This continued for fully two days, during which she remained on duty, but in the evening of the second day she was forced to go to bed on account of the intensity of headache and backache; there were now present also anginal symptoms; the face was flushed, and there was noted by the nurse who looked after the patient a generalized erythema, which seemed to be typically scarlatinal. The pharynx was congested, but there was no membrane. The temperature at this time was 103.8° F. On the following morning (Jan. 23) she entered the service of Dr. Baum, in ward 26. Examination showed a well-nourished and well-developed young woman; she is somewhat exhausted, but not in any special distress and clear mentally. On the neck and chest is a diffuse red rash with punctiform spots. Mouth and lips dry, tongue brownish, fissured. Tonsils prominent, faucial pillars congested, no membrane. The cervical glands appear a little large. Thoracic organs apparently normal. The patient complains of tenderness on palpation of the abdomen, most marked in the iliac region; the abdominal walls are somewhat rigid. Spleen not palpable. Blood cultures were made Jan. 26, three days after admission, five drops of blood being added to each of two flasks containing 50 c.c. plain bouillon. In both there developed pure growths of typhoid bacillus. This bacillus was agglutinated by typhoid serum. A few days later the patient's serum was found to agglutinate typhoid bacilli. The patient passed through a severe attack of typhoid fever, ending in recovery. She *did not desquamate.* The patient gave a history of measles and whooping-cough and exposure to scarlet fever when a child while an older sister was sick with that disease; but the mother does not think that she had any eruption.

In these two cases I have taken it for granted that there was not sufficient evidence in either one to warrant the diagnosis of scarlet fever. Yet, if we assume that mild cases of scarlet fever occasionally may not be followed by desquamation the claim that in both these instances it actually concerned scarlet fever associated with typhoid fever perhaps could not be disproven with absolute success. So long as it is not possible to place the diagnosis of scarlet fever upon an absolute etiological basis there always must be more or less room to question the real nature of scarlatiniform diseases, especially in patients not giving a clear history of previous attacks of typical scarlatina.



Case III.—Temperature Chart.

In neither of these cases was it possible to obtain any information of the use by the patients of any drugs that might have caused the misleading rashes.

Text-books in general mention the occasional presence of erythema in typhoid. Osler says: "It is not very uncommon in the first week of the disease to find a diffuse erythematous blush—E. typhosus. Formerly we thought it might be due to quinine."* Eichhorst† cautions against mistaking the diffuse typhoid erythema occasionally seen on the chest and abdomen, more rarely on the extremities, for scarlatina. This mistake

* Osler, fourth edition, 1902, p. 17.
† Handbuch, 1891, IV, 382.

he says is especially likely to occur when angina* is present. According to Curschmann,† Jenner (who mentions a case of typhoid fever mistaken for scarlet fever), Raymond, Le Maigre, and others, have described scarlatiniform eruptions in typhoid fever. These eruptions Curschmann is inclined to regard as medicamentous in nature.

But the most important statement that I know of concerning scarlatiniform and other anomalous rashes in typhoid fever is the aforementioned article by Da Costa. He points out that the scarlatiniform rash may remain throughout the fever, but this is rare; it may come out late, even in convalescence, and return in relapse; for the most part it is connected with angina. It passes away without desquamation. "Save under the exceptional circumstances of attending sore throat and desquamation there is no difficulty in determining the two diseases, or in diagnosticating that scarlet fever is not intercurrent in typhoid." Da Costa also discusses a more uncommon measles-like rash in typhoid fever, and details a case of the intercurrence of true measles in typhoid. Finally he mentions the combination and interchangeability of the scarlatiniform and the measles rashes in enteric fever.

The special point that I wish to emphasize again is that the practically constant presence of typhoid bacilli in the blood in the early stages, during the height, and at the beginning of relapses of typhoid fever, renders it possible by the use of proper cultural methods to settle promptly the diagnosis of typhoid fever in peculiar cases like those just reported. The indications are that this statement also holds true in paratyphoid fever.

---

## TYPHOID FEVER IN INFANCY AND CHILDHOOD.‡

BY J. P. CROZER GRIFFITH, M.D.,
OF PHILADELPHIA.

THERE has been created in recent years a large literature in medical journals and text-books treating of typhoid fever in infancy and early life. Over my own signature there have appeared a few contributions on the subject, and I have but little new to add to these. It has seemed best to me, therefore, to make little, if any, direct reference to the contributions of individual writers, since this would consume far more time than the limited amount at my disposal, but, dwelling only on the peculiarities of the disease as seen in early life, to give only a synopsis of what is generally admitted by writers, combined with the results of my own experience, which has been somewhat extended.

*Etiology.*—The cause of typhoid fever in infancy and childhood is, of course, the same as in later years, *i.e.*, the action upon the system of a specific infectious germ. The usual method of entrance, too, is the same, viz., by the intestinal tract, in the case of infants and children particularly emphasized by the number of milk epidemics which have been reported. A number of cases are recorded, however, in which the disease was clearly contracted in fetal life. Writing in 1898 (*Philadelphia Medical Journal*, October 15), I found in medical literature 10 cases which could properly be called *fetal typhoid* in the sense that a typhoid mother gave birth to a fetus stillborn or dying shortly after birth, the typhoid bacilli being recognized by modern methods. Later Morse added cases from literature to the list. Including such of these instances of fetal typhoid as have been born alive although dying shortly afterward, as well as those which have shown symptoms of the disease very shortly after birth and have recovered, Dr. Ostheimer and myself, in a recent article (*American Journal of Medical Sciences*, November, 1902), have published 23 cases collected from medical literature which have been considered by the reporters to be suffering from typhoid fever, and which may be called *congenital typhoid* fever. Not all of these are undoubted instances of the disease. In fact, some of them are more than doubtful. But a considerable number are unquestionable. In all these instances of fetal or congenital typhoid fever it is evident that the bacillus was acquired not in the ordinary manner, but by the way of the placental circulation.

As regards the influence of age on the production of the disease as acquired in the ordinary method, there has been of recent years much dispute. It is curious to notice the change which appears gradually to be creeping over the sentiments of the profession in this country on this point. In 1892 a paper was read by Christopher, before the American Pediatric Society, upon typhoid in early life. In the course of discussion the expression was almost unanimous that the occurrence of the disease in infancy was extremely rare. In 1900 Blackader read another paper before the Society on the same subject. It was evident in the discussion at this time that the earlier belief was becoming much shaken. Last year the paper already referred to was presented by Ostheimer and myself. A still further wavering in the opinion of the members seemed evident.

My own belief, as expressed in the article referred to, is that the disease is far less rare in infancy and early childhood than has been generally supposed. With the greater care in observation, and especially by the aid of the serum reaction, it has become evident that the immunity of infants is not so great. Not that cases at this period are by any means as frequent as later in life, but that they occur far too often to allow us to call the affection absolutely rare. We have detailed 18 personal cases, observed by ourselves, or, in a few instances, by colleagues and not published previously, of typhoid fever in children up to the age of 2½ years. Including these with others published in medical literature, we have collected 139 cases occurring in the first year of life. Add-

* The occurrence now and then of angina in the beginning of typhoid fever suggests that the tonsils may be one port of entrance of typhoid bacilli into the blood.
† Loc. cit., p. 114.
‡ Read before the New York Academy of Medicine.

ing the congenital cases, we have in all 162 cases in the first year. As before stated, some of these cases are doubtless mistaken diagnoses and are open to question, but in the large majority of instances there appears to be no reason to doubt the diagnosis.

The principal cause of the relative immunity in earliest life I believe to be chiefly, if not solely, the lesser frequency with which typhoid bacilli enter the gastro-intestinal tract. The breast-fed children naturally are largely exempt, and the very common practice of subjecting the food to a degree of heat destructive of the bacillus, prevents the occurrence of the disease in artificially-fed children. Yet, when in any case it appears impossible to the family or to the physician that infection could have occurred, we must not forget the practice, not as common as it should be with proper precautions, of giving infants *water* to drink.

*Symptomatology.*—As compared with the symptomatology of the disease as seen in adult life the two chief characteristics of typhoid fever in infancy and childhood are (1) the less typical onset and course, and (2) the tendency of nervous symptoms to overbalance intestinal ones. It is particularly in the first two years of life that we are liable to be misled. I have seen more than one case in the first year proven to be typhoid fever, yet without any of the cardinal symptoms being present. In general we may say that in infancy the disease is liable to be atypical in most particulars; in early childhood and the first part of later childhood it shows the usual symptoms greatly modified; while in the latter part of later childhood, say, from the age of nine to that of twelve years, the symptoms approach much more nearly to those of adult life. The description which follows applies especially to the disease as occurring in early childhood.

We may review briefly some of the important symptoms. The *onset* is frequently slow and insidious, even more so than in adult life. My experience in the Out-Patient Department of the Children's Hospital shows me every year children brought for a number of visits, feeling very little ill and quite able to walk to the Dispensary. It might be only after repeated visits that the finding of rose spots or enlarged spleen, or the discovery of a Widal reaction, would settle the question of diagnosis. Then the child would be sent home and ordered to be kept in bed, not because it felt ill, but because the physician wished it. These walking cases of typhoid are, I believe, far more common than in adults.

On the other hand, it is certainly true that the onset of typhoid is at times remarkably sudden in children. The temperature may rise quite rapidly and the attack be well under way in only a few days, the initial symptoms being sometimes remarkably severe.

*Vomiting* is a comparatively common initial symptom in childhood. This, the experience of most observers, corresponds with my own. Rarely does it give any great trouble at any time in the course of the disease, but I can recall one case fatal apparently from uncontrollable vomiting coming on later in an attack which had, up to that time, been rather mild.

*Epistaxis* is probably not as frequent as in adults. This has certainly been my own experience at least. In one instance, however, in a girl eight or nine years old, I saw it followed by death. Some degree of *cough* is common, with the presence of coarse mucous râles in the chest. I have not often, however, found the cough troublesome, as it not infrequently is during the initial symptoms of typhoid fever in adults.

As regards the state of the *bowels*, the statistics of the cases collected by Ostheimer and myself show that diarrhea is a not infrequent symptom of the disease occurring in the first 2½ years of life. In the 417 cases in our report diarrhea is said to have been present in but 113, yet it was doubtless present, but not referred to, in others. The frequency in infancy must certainly be due to the tendency which the intestine shows in early life to exhibit diarrhea, dependent upon even slight congestive conditions. In early childhood the infrequency of diarrhea is probably to be attributed to the well-known fact that ulceration is far less marked, as a rule, at this period than later in life. Even in later childhood diarrhea has certainly been in my experience a symptom giving comparatively little trouble. Yet, I have occasionally seen cases where it was a most troublesome and debilitating symptom, and some published statistics show it to be perhaps as common as constipation. It is a curious fact that during the present winter season diarrhea has been unusually prevalent in the cases in the Children's Hospital of Philadelphia. This may be due to the fact that the great majority of our cases this year have occurred in children of from eight to twelve years of age. In the 71 cases occurring in the Children's Hospital in 1901, analyzed by Hand and Walker (*American Journal of Medical Sciences*, June, 1902), diarrhea occurred in 27.

*Abdominal Pain* is not infrequent, but great tympanitic distress is, in my experience, unusual. It is only rarely that it requires special treatment.

*Rose Spots* are probably present in the majority of cases. The frequency with which these are found will probably depend on the carefulness with which they are repeatedly sought for. I doubt whether there is much difference in the frequency of occurrence in children, as compared with that in adults. I have seen the spots so thickly covering the body, including the face, in a child of five that the disease suggested measles, and I have seen an equal development in an adult male. The same statement is true of the discovering of *enlargement of the spleen*. The organ is probably always enlarged. It could be detected in the great majority of my cases. Regarding the *desquamation*, on which stress has been laid by Weill and others, although it has been very often observed in my cases, I have not

been able to convince myself that it was in any way characteristic.

As already stated, the *nervous symptoms* of typhoid tend to preponderate over the intestinal in children. This expresses a relation only, and does not mean that they are actually very marked. On the contrary, the coma, subsultus, dry, brown tongue, muttering delirium and other symptoms of the advanced typhoid state seen so often in adults are much less often observed in childhood. Only in those children not many years removed from puberty are these severe symptoms apt to be found. I have quite recently seen a child of eight years in which there was profound unconsciousness, muttering delirium and very dry tongue, in fact, the typical symptoms of the advanced typhoid state; but this is the only case which now comes to my recollection. There is generally a certain slight degree of apathy which is quite characteristic. A slight delirium, especially at night, is common. Headache is a frequent initial symptom, but not to the degree seen in adults. One form of nervous disturbance appears more apt to occur than in later life, viz., an initial wild delirium which strongly suggests meningitis. I have for a time been misled entirely in diagnosis by such an occurrence. In fact, the occurrence of a pseudomeningitis I believe to be much more frequent than in adult life. I have now under my care just such a case, in a girl of five years. The patient developed an obstinate convulsive state on the third day of recognized symptoms, and then passed into an unconscious condition. Meningitis appeared the most probable diagnosis, and only the Widal reaction made the true nature of the disease manifest.

As regards *renal* symptoms there is probably no difference as compared with those of adult life.

As to the *duration* of the attack and the course of the disease in general, the total average duration may be stated as from fourteen to twenty-one days, although often a little longer, the attack being generally severer and more prolonged in proportion as the child is older. Of course there are exceptions, and fever may continue even for five or six weeks. The temperature usually rises rapidly, remaining high with very little variation between the morning and the evening elevation. It falls much more rapidly than in adults, the intermittent temperature of the last portion of adult typhoid being generally much less marked, greatly curtailed, or entirely absent. In some cases the fall is almost critical in type. In infancy the temperature is liable to be exceedingly irregular. Not infrequently in childhood there is a tendency for a moderately irregular elevation of temperature to persist for, it may be, weeks after all other symptoms have disappeared. This occurs also in adults, as is well known, and, I believe, with about the same frequency.

Regarding the *pathological anatomy*, the spleen is always enlarged, and the mesenteric glands are liable to be much swollen. This latter has been regarded by some writers as especially characteristic of the disease in childhood. The solitary and agminated glands exhibit a decidely hyperplastic condition, the glands becoming pinkish and projecting above the lumen of the intestines; but there is, as stated, as a rule, a very much lesser tendency to ulceration. When ulceration does occur, it tends to be superficial only. This applies especially to infancy and early childhood, but is open to exception. In later childhood the tendency to ulceration increases, and I have seen it very extensive even in children of from six to eight years. This is, however, exceptional. It is probably due to the presence of less marked intestinal lesions that the course of typhoid fever is shorter in childhood, and that the temperature falls more rapidly. It is an interesting fact that in none of the cases of typhoid fever in the fetus which I collected was there any involvement of the intestine whatever.

*Diagnosis.*—The diagnosis in infancy is difficult. The irregular character of the pyrexia of typhoid fever at this time of life, the tendency for any catarrhal state of the intestine to be attended by fever and diarrhea, and the fact, proven by autopsies, that inflammation of the intestinal glands may attend equally well typhoid fever and enterocolitis, make it at times impossible to come to a satisfactory conclusion. The value of the Widal serum reaction is inestimable at this period of life. In later infancy and early and later childhood the diagnosis still offers difficulties. Meningitis is to be carefully excluded. As time passes this difficulty is generally removed, since the early meningeal symptoms sometimes present rarely continue. Enterocolitis can usually be distinguished after a little time. Influenza offers peculiar difficulties. There is in it, as in typhoid fever, the continuation of pyrexia without discoverable cause sufficient to explain it. A leucocyte count helps to a great extent in many conditions, but not in distinguishing between these two diseases. The development finally of a serum reaction settles the question, if the finding of rose spots and an enlarged spleen has not done so already. We must not feel, however, that the failure of the serum reaction to show itself is proof that typhoid fever is absent. The reaction may be very late in arriving. For instance, in one undoubted case occurring in the Children's Hospital it was not obtained until the twenty-seventh day.

Of the *complications* and *sequels* I have only a few words to say, and these are especially to emphasize the absence of some of them. The various other infectious diseases may occur simultaneously with or consecutively to typhoid fever. I have seen this true of scarlet fever, of diphtheria and of measles. Aphasia is a sequel said to occur oftener after typhoid fever in childhood than in adult life. Personally I have seen little of it. Posttyphoidal insanity is a rare sequel. I have seen it in but two cases. Some very interesting examples are reported in medical litera-

ture. Noma is an unusual complication seen in childhood. I have observed it in several instances. Intestinal hemorrhage is generally considered to be marked by its infrequency. This is especially true of infancy and early childhood. I have, however, seen it in the case of a five-months'-old patient. In later childhood it is more common, although much less so than in adults. Still we have it occurring not so infrequently in our Children's Hospital cases. It was present in 4 of the 71 Children's Hospital cases of 1901. Generally it is very slight, but I have seen it exceedingly severe in two cases in the last two winters. Perforation, too, is generally admitted to be of great rarity in childhood. This is undoubtedly true, and I have been peculiarly unfortunate in meeting it in 4 cases, in children of eight, ten, eleven and twelve years, respectively. One of these cases was operated on; two others came to autopsy; in one the diagnosis was practically positive, although operation was refused and no autopsy possible.

*Relapse* would appear to be about as frequent as in adult life. It varies, of course, with the epidemic, and with the individual experience of the observer. It occurred in 6, *i.e.*, 8.5 per cent., of the 71 Children's Hospital cases referred to.

The *prognosis* is, on the whole, good in children. Of 137 cases occurring during ten years in the Children's Hospital up to 1898 only 3 died, a mortality of 2.9 per cent. Doubtless there were many other cases which recovered, although unrecognized, the true diagnosis of which more recent methods would have made plain. In the years 1898 to 1902, inclusive, there were 295 cases, and of these 20 died, a mortality of 6.7 per cent. The total mortality in 432 cases was 23, a death-rate of 5.32 per cent. The mortality of the 278 cases of 2½ years and less in which the result is stated contained in the collection of Ostheimer and myself, was unusually high, equaling 51 per cent. This would appear to indicate that the number of fatal cases is exceptionally high at this period of life. I am convinced, however, that the figures are to a considerable extent misleading, as the unusually severe and especially the fatal cases are the ones physicians are most liable to report. However, of our 18 personal cases of 2½ years and less, 5 died, a mortality of 27.77 per cent. The number observed is, of course, too small to allow of any conclusions being drawn. Nevertheless, it tends to make me change my former view, and to regard typhoid fever in infancy as a distinctly dangerous disease. This, however, needs further study. In early childhood the prognosis of the disease is certainly good.

*Treatment.*—In the present method of making hydrotherapy practically the only therapeutics of typhoid fever, except purely symptomatic treatment, the question is a vital one as to how far the method applies to the disease as occurring in children. Although valuable, hydrotherapy must be used with much caution, and the method of Brandt, carried out in its exactness, is seldom applicable. In my experience the true cool or cold bath occupies but little place at this time of life. Children, as a rule, do not tolerate it well. This is especially true of younger children. Even the tepid plunge of 85° to 90° F., or the graduated bath, is often not well borne, even by older children. I have repeatedly had to abandon it on account of the weakness of pulse which it produced. My custom is to employ sponging first, since this is often quite sufficient. If it is not, then the graduated bath of 90° cooled down to 80° F. is employed. In some instances I have had excellent results from the warm tub bath of 95° to 100° F. In many instances I have found the application of an abdominal ice-bag extremely serviceable in reducing temperature.

It is noteworthy that very often sponging seems to do harm. In many such cases tubbing is to be preferred to sponging on account not only of its greater power, but especially of its shorter duration. To sponge a child for fifteen minutes who is crying and struggling violently meanwhile is of very questionable good. A brief immersion in the bath is often far less fatiguing to the patient.

We must remember that children, as a rule, not only develop high temperatures readily, but that they tolerate this unusually well. We can, therefore, in many cases, afford to let the temperature alone. Careful judgment must be employed, and hydrotherapy can never be used in children as a necessary routine. Although so valuable in many cases, it is, without the exercise of judgment, often capable of doing far more harm than good.

---

## NOURISHMENT, MEDICATION, HYDROTHERAPY, AND GENERAL MANAGEMENT OF TYPHOID FEVER CASES.

BY W. T. BAKER, M.D.,
OF MIDLOTHIAN, TEXAS.

The subject which I have selected is not by any means a new one, nor do I anticipate the giving to this enlightened body any new theories; but I wish to impress the importance of doing the things thoroughly well which we all know how to do and perhaps in a measure have done.

In the first place, according to our present knowledge, in typhoid fever we have a disease which is largely, if not entirely, a self-limited disease; one for which we have no specific medical or other antidote, or can by any other procedure limit the disease to a shorter period than three weeks, and in some cases longer. However, I do believe that, in a very large per cent. of our cases, we should limit the febrile course to three weeks or thereabouts—say, within twenty-five days. I shall not say that this or that thing is the *most important* to do for a typhoid fever patient; but rather that any and all things done should be most important, and if a thing is not important, why do it at all? Right here I wish to say, parenthetically, that there is a tendency upon the part

of the laity, if not the physician, to do unimportant things which many times are detrimental to our patients.

As I have indicated in the naming of my subject, there are four special divisions of it, which I shall mention in the order in which they are given in the subject heading, which begins with

*Nourishment.*—It is one thing to say what our patients shall eat, and another thing to get them to eat it. Then comes the all-important question of determining what they can eat with impunity and what is contra-indicated in an individual case. I have found that every case is individual in some respects, and should be treated as such. The old idea that typhoid fever patients should be fed on strained soups, buttermilk, malted milk, and such like is an erroneous idea and should be corrected. In the first place, they do not give a sufficient variety, are soon tired of, and are not very palatable; therefore, you cannot get the patient to take sufficient amount of these to get the desired amount of nourishment, and unless the patient will take the nourishment prescribed, it had as well not have been prescribed, so far as the results are concerned. Therefore, we must select something our patients can and will eat, and at the same time not be contra-indicated, and yet nourishing to our patient; for, as I stated at the first, it is *most important* that our patient should be kept well nourished. So I say to the nurse, feed the patient; give him buttermilk, most any kind of meat soups, plain or thickened with a little flour if desired; rice, oatmeal, wheatlet or any wheat preparation, XXX crackers, baker's bread in form of toast, with butter or softened with milk or hot water, or patient may eat it dry from the oven, chewing it up well and swallowing it with plenty of drinking water; a young chicken or a tender rabbit or bird made with soup, and cooked until very tender; most any kind of preserves or jelly, excluding the hard, lumpy portions, and things having seeds, such as blackberries; the syrup and the softer parts of canned fruits may be given, such as peaches or apricots; a baked apple; a well-ripe tomato, all but the skin and the hard core; an Irish potato that has been out of the ground long enough to be well dried out, and baked till it will mash up. All of these things which have been mentioned that require cooking, I recommend that they be thoroughly done before the patient should eat them, and, of course, should be seasoned according to taste. Now, from the things enumerated, you see I have a sufficient number to give a variety of nourishment; and from the whole some things can be selected which are to a certain degree palatable, or at least can be forced upon the stomach of most patients sufficient to accomplish a very good degree of nourishment; while, on the other hand, the absolute fluid diet soon tires the patient, and you fail to do the *most important* thing, viz., nourish your patient. I am aware that some may say that in my allowance of foodstuffs there is too much effete matter, that the bolus formed in the intestinal tract would do material harm to it as it passes through; but the facts in the case are (I think) to the contrary. As none of the articles I mentioned would become hard, dry masses in the intestinal tract, but would be soft, mush-like masses, which do not overdistend the bowels and do them harm, but to the contrary benefit them by wiping off the mucous membrane of the surface over which they pass, clearing off all discharges from the ulcerating patches, thus giving opportunity to get a local antiseptic or absorbent, or filling in effect of any drug which you may be administering, should you be fortunate enough to reach these ulcerating patches with such drugs. Also the frequent separation of one wall of the ulcerating gut from the other furnishes free drainage for the same, and these things prevent the ulcers from going so deep into the intestinal wall, as they no doubt would by laying one upon another, in doing this you often prevent hemorrhage; on the other hand, the gases which necessarily accumulate where such drainage has not been accomplished, will in many cases produce such distention of the bowels as to cause very serious and oftentimes fatal hemorrhage. So that, leaving out the question of palatability and nourishment altogether, I think, the effect on the bowels locally, from a mechanical point of view, is very much in favor of such things as will make an effete mass. When you come to the point of considering both nourishment and drainage, there can be no question as to the propriety and desirability of this plan of feeding. Then there is a humane side of this question: When patients are fed on liquid diet they become so emaciated that when the time does come for an appetite, some of them suffer inexpressible hunger, which cannot be satisfied, and their very bones and muscles cry out in pain for the needed nourishment; and should the patient get hold of something to eat his hunger is so great that he will not resist it, even though it be a thing that a well man ought not to eat. And then and there we have a relapse, which means a long and tedious spell for the patient and doctor, if not a funeral, whereas if the patient is well nourished all the way through, the fever period is shortened, the hunger is not so distressing nor uncontrollable. The patient gets right out of bed in a day or so after the fever is gone; takes the necessary exercise and fresh air and is soon well.

*Medication* is the second topic mentioned in my subject; and as I have disallowed of specifics in the outset, it will necessarily leave me to recommend the use of such drugs as will best meet the indications, as they appear from the time the patient is first seen. A large percentage of my patients need at first a good, thorough cleaning out; a stimulation of the secretions, and for this purpose I usually use the mild chloride of mercury with bicarbonate of soda, given in grain doses an hour apart until three or four are given, repeated the third or fourth night, as the indications may demand. I sometimes add podophyllin or rhubarb to this, especially if after

the first night I fail to get good results. If the fever is high and the patient is aching, as many of them do, I give them at first a prescription containing codeine, phenacetine, salol and quinine to last three or four days, to be given in daytime, continued through the night if the patient does not rest. In addition to this I give carbolic acid minims 1, tincture of iodine minims 2, and aqua drams 1, every four hours in daytime for its antiseptic effect, and this I continue throughout the fever period unless for some reason I need to give an absorbent, and then I give one that is also an antiseptic. I have used resor-bisnol with very happy results, or in case the carbolic acid and iodine are very distasteful to the patient, I use any other good antiseptic. When I have given enough quinine to be sure I have overcome all malaria and the pain has subsided so I can leave off the codeine and phenacetine, I continue the salol by giving about six grains, three times a day, together with bicarbonate of soda and about one-eighth grain of the mild chloride of mercury; this makes up my routine of dosage throughout the fever period with the addition of strychnine to the liquid solution, as soon as indicated by the pulse; thus you see, I have a capsule and a teaspoonful of the antiseptic solution every four hours in daytime. That is all the medicine my patient has to take, unless a dose to relieve pain, quiet nervousness, to produce sleep, or meet any such conditions which might arise and, of course, when I begin the use of strychnine, I arrange my antiseptic solution in dosage and time to suit it. Before leaving the subject of medication, I wish to say that I have read with interest some very favorable reports from the use of acetozone as an intestinal antiseptic in typhoid fever, as well as other intestinal troubles; but as yet have not tried it myself. However, I recommend a careful study of the reports of this new antiseptic and its adoption as soon as its virtues are proven superior to those now in use. I also have a hope that the serum treatment may prove a great success. I go into the details of my medication chiefly to show its simplicity and conservatism. I do not give drugs except to accomplish certain ends; and believe many times in an effort to cure the patient, very many doses and drugs are given which do the patient actual harm.

*Hydrotherapy.*—This is a most important part of the treatment, and I use it in all the ways with which I am acquainted, to accomplish the purposes for which it is indicated. Some of which are to quench the thirst, furnish water to the fever-dried tissues, to keep the temperature from reaching and remaining at a harmful height, thus preventing nervousness and delirium, and sustaining the heart, for all of which I prefer the water cold. I sponge them, plunge them, and pack them; usually preferring the latter; am not much in sympathy with the plan of pouring ice water over the head, to the neglect of the other portions of the body.

*General Management.*—This is the last theme mentioned in my subject, yet it is a very important part of the treatment. Much could be written upon this subject, but I shall endeavor to be as brief as possible to give you such ideas as I have in mind. First, if possible, I want a nurse that is strong enough in body and mind to carry out my instructions, one who does not *know all about nursing sick folks.* I want my patient fed at regular intervals, say about every two and a half to four hours in daytime and as often at night, if awake, but do not want them awakened to give nourishment as long as they are reasonably strong. I want the nurse to sleep in the room with the patient, but not to sit up with him as long as he is rational; and it is not necessary to sit up and give medicine or control fever. I want business matters and other things that are liable to worry kept away from him; do not want all the kin, the neighbors, their children and their dogs to call on him or stay about the place; want his bedding changed, in mild cases, every second day, or, if fever is very high, every twenty-four hours. The urine, effete matter and what he spits or vomits should be disinfected and removed from the room at once; the room kept well ventilated and cleaned, with plenty of light; quiet maintained day and night. The patient should know enough of the current happenings of the outside world to give him something to think of and keep him from being too lonesome or from thinking too much of business or other matters.

Now, in conclusion, I wish to say I have written as for the average case and patient which I vary according to the severity of case, and general surroundings. The dosage is for the average adult, children in proportion. Herewith I wish to give you a tabulated report of thirty-one cases treated after the plan outlined, which, I think, strengthens very materially the points which I have endeavored to make, and these cases are just as they came to me in my general practice.

From this report you will notice I have only had one case of hemorrhage; and it was a case where the patient had been treated for two weeks by a druggist with purgative pills and quinine. The patient had not remained in bed until after the hemorrhage, when I was sent for, which was five days before he died. You will also observe that there are only two deaths, one of these the case just mentioned; the other a case of reinfection, a girl, in which there were other complications, accounted for by her time of life. There were only two cases of reinfection, one of which, after having fever fifty-two days, got out of her bed, put on her clothes and walked across the floor through a hall and sat down at the top of a flight of stairs to talk; all of which she did without the aid of any one; this being the last day of fever; and the fourth day after the fever was gone, she went down stairs for her meals at her boarding house, and continued to do so thereafter. And before another month had elapsed she was in her place as teacher in one of the public schools of Dallas, where she has continued to teach until this time. Another one of my patients

was a young lady, eighteen years old, whose fever stopped on the twenty-first day; the third day after the fever left her she walked a distance of four blocks to where a new flour mill was being built, and in company with two other girls went into the basement and up a flight of skeleton stairs to the top of the fourth floor, and back again to town and back home, making in all an absence of about an hour, after which she said she was not very tired, and from which exercise there were no apparent bad effects. I did not know of this trip until after it was made, nor did I approve of it.

I make particular mention of these two cases to show how well the strength may be maintained by proper nourishment, even though they have high fevers and long fever periods. The young lady who took such a risk by going to the mill and to town, had a temperature running up to 104.5° F. for several days, though the most of the time 103° F. would represent the highest temperature; and the temperature of the other lady, specially mentioned in regard to her strength, reached 106° F. the second and third days after her relapse, which occurred on the twentieth day of her fever.

REPORT OF CASES.

| Name | Sex | Age | Month | Called | Duration | Remarks |
|---|---|---|---|---|---|---|
| V. K. | Male | 19 | May | 5 | 33 days | Complicated by hyperemic spleen |
| J. B. | male | 26 | June | 4 | 28 days | |
| W. L. H. | male | 6 | June | 5 | 21 days | |
| C. V. | male | 38 | June | 4 | 23 days | |
| * * | female | 7 | June | 3 | 21 days | |
| J. C. Mc. | male | 49 | July | 1 | 21 days | |
| Mrs. W. | female | 37 | July | 4 | 25 days | |
| W. W. | female | 15 | July | 4 | 35 days | Complicated by malaria |
| C. C. | female | 14 | July | 1 | 32 days | Died |
| N. B. | female | 18 | August | 3 | 21 days | Walk to new mill, etc. |
| B. | female | 14 | August | 1 | 20 days | |
| Jim C. | male | 28 | August | 6 | 21 days | |
| H. D. | male | 8 | August | 2 | 22 days | |
| C. H. | male | 8 | August | 4 | 21 days | |
| C. H. | male | 6 | August | 4 | 21 days | |
| J. M. L. | female | 7 | August | 6 | 22 days | |
| C. B. | male | 11 | August | 1 | 18 days | |
| C. B. | female | 9 | August | 1 | 20 days | In school in one week |
| B. A. | female | 8 | September | 4 | 23 days | |
| Miss C. G. | female | 24 | September | 3 | 52 days | Reinfected on the twentieth day, temperature reaching 106°F. for two days; walked to stairs day fever broke; in four days went to meals from stairs. |
| B. | female | 12 | September | 1 | 23 days | |
| B. | female | 10 | September | 1 | 21 days | |
| M. M. | female | 16 | September | 5 | 22 days | |
| C. W. S. | male | 40 | September | 7 | 23 days | |
| J. H. | male | 31 | September | 7 | 21 days | |
| B. | male | 6 | October | 1 | 28 days | |
| J. T. M. | male | 11 | October | 2 | 35 days | |
| C. C. | male | 20 | November | 7 | 23 days | |
| M. B. | female | 12 | November | 6 | 24 days | |
| W. G. | male | 31 | December | 2 | 22 days | Very sick |
| Chas. L. | male | 33 | December | 15 | 20 days | Died, result of hemorrhage |

I trust I have not worried anyone by the statement of the details of my cases and their treatment. But on the other hand that I have impressed your minds with the necessity of liberal nourishment, restricted medication, abundant use of water, and strict carefulness in the general management of this kind of cases. I have never had a relapse or any discoverable discomfort from my feeding; on the other hand, when I have been unable to feed my patients as I desired I have observed a longer term of convalescence, and usually a lengthening of the fever period.

---

## THE ETIOLOGY AND CHEMICAL PATHOLOGY OF GALL-STONES.

BY C. A. HERTER, M.D.,
OF NEW YORK.

(Continued from Page 536.)

*Biliary Infection in Cholelithiasis.*—The presence of bacteria in the bile of cholelithiasis patients is a very common but by no means regular occurrence. W. Peterson* in fifty operations for gall-stones found bacteria in the bile 44 times. In 36 instances the *Bacillus coli* was found, 6 times this bacillus was associated with the *Staphylococcus aureus*, and in 4 cases the *Streptococcus pyogenes* was the companion of the *Bacillus coli*.

These figures are probably fairly representative of the cases of cholelithiasis that call for operative interference, although no typhoidal infections happen to occur in Peterson's group of cases. It should be remembered, however, that the character of the gall-bladder infection does not necessarily represent the infective agent concerned with the production of the gall-stone, for it may happen that a stone referable to typhoid infection is the means of provoking a cholecystitis due to another organism, long after the original inflammation of the gall-bladder has subsided. Sometimes the bile is sterile, although stones taken from the same bladder contain living bacteria. On the other hand a stone from which no organisms can be cultivated is sometimes associated with bile from which bacteria can be grown.

*Influence of Human Biliary Stagnation.*—It has already been mentioned that an essential condition for the production of experimental cholelithiasis is some degree of impairment of the expulsive power of the gall-bladder. In the absence of such impairment it appears to be extremely difficult for bacteria to gain and maintain a foothold in the healthy gall-bladder. Myake found that ligation of the cystic duct does not lead to infection of the cystic bile, presumably because the unchecked bile flow into the intestine suffices to wash back entering bacteria and to limit their spread.† On the other hand ligation of the ductus choledochus was followed by infection of the cystic bile, because this operation which lies within the normal bacterial zone,‡ completely stops the bile stream to the duodenum. The results of Ehret and Stolz differ from those of Myake in regard to the consequences of ligation of the cystic duct. These ob-

*Brun's Beiträge, Bd. 23.

†Atrophy of the bladder from ligation of the cystic artery is a result of this operation.

‡According to Netter and Duclaux, in dogs and rabbits only the lower part of the ductus choledochus (near the papilla) is ordinarily inhabited by bacteria.

servers found that even after the cystic duct had been severed between two ligatures there was a pronounced increase in the number of organisms present in the bile.* As these organisms could not have come from the intestine it is necessary to assume that they arose from the multiplication of bacteria already present in the gall-bladder or possibly that they came from the blood. The eventual death of these organisms appears referable to their feeble powers of adaptation rather than to any increase of the bactericidal action of the bile.

Thus, it is likely that while the mere stagnation of the cystic bile may not always be followed by infection of the gall-bladder, such stagnation greatly increases the chance that bacteria will establish themselves in this locality. The information derived from experimentation upon animals makes it extremely probable that whatever causes cystic stagnation in man, increases the opportunity for infection and consequently of cholelithiasis. Among the conditions that lead to impaired expulsion of the cystic bile are the atrophy of the muscular coat of the gall-bladder and various mechanical agencies which obstruct the biliary passages. The increased liability to gall-stone in old age probably depends in a measure on the weakening of the muscular coat of the gall-bladder, but a diminished resistance of the body fluids to infectious agents is possibly another factor. The greater incidence of gall-stones in women has been attributed to the mechanical hindrance to the expulsion of bile from the gall-bladder caused by tight lacing. Probably tight lacing acts as such a hindrance, but it fails to explain the liability of the women who do not lace.

It is stated that in fever the gall-bladder is emptied with less completeness than in health, but the evidence in favor of this view is not satisfactory. That the gall-bladder is distended with excessively watery bile in many cases of typhoid fever is well known to pathologists, and it is highly probable that this overdistention is connected with a paretic state of the muscular layer. But it is much more likely that this is a result rather than a cause of infection. Whether fever is in itself a cause of muscular relaxation must be regarded as an open question.

It may therefore be said that while experimental evidence makes it highly probable that hindrance to the normal bile-flow from the gall-bladder facilitates infection of the human gall-bladder, our knowledge of the disturbances of cystic function that cause biliary stones is still incomplete.

*Mode of Action of Bacteria.*—There are two ways in which we may conceive gall-bladder infection to operate in the production of gall-stones, first by setting up cholecystitis, secondly by causing a decomposition of the bile. Although these processes are probably connected closely, we must consider them individually.

*It will be recalled that these investigators found bacteria much oftener in the bile of normal animals than have other writers.

*Cholecystitis and Its Effects.*—One of the consequences of a slight or moderate catarrhal cholecystitis is the proliferation, desquamation and degeneration of epithelial cells. These cells contain cholesterin, a part of which ultimately finds its way into the bile. Probably the quantity of cholesterin increases as time passes, owing to degenerative changes in the cells, the nature of which is obscure. It is well known that pus contains considerable cholesterin and that crystals of cholesterin are more apt to occur in old than in fresh pus. The cause of the increased production is not understood but is to be sought either in cleavages induced by bacteria or in ontolytic decompositions. The same may be said of the cholesterin of epithelial origin. The desquamated epithelium contains some calcium, but whether the calcium of gall-stones has this origin or is derived from mucus, is not clear. A careful study of the influence of cholecystitis on the calcium of the bile is a desideratum.

It is noteworthy that in their observations on purulent cholecystitis Ehret and Stolz were unable to find any indications of the presence of cholesterin in the contents of the gall-bladder.

*Decomposition of the Bile.*—In the course of any infection leading to cholecystitis the bile is liable to undergo decomposition. This is very plainly seen in typhoid fever, in the course of which a large part of the bilirubin is apt to be destroyed. The nature of the decomposition products is unknown and its study would surely lead to results of considerable interest. In purulent cholecystitis, also, the bilirubin disappears, often very rapidly, so that all traces of color may be lost in two or three days. Even in milder types of inflammation, such as commonly lead to cholelithiasis there is often a decomposition of the bile, the nature of the cleavage products being, however, but imperfectly understood. The presence of bilifuscin and bilicyrin in some gall-stones is probably to be regarded as an indication of decomposition of the biliary pigments. It is believed that the bile acids also undergo decomposition at times, with liberation of cholalic acid.

Whether these decompositions are the immediate result of the growth of bacteria in the bile or an indirect effect of altered secretory conditions of the inflamed mucosa is uncertain, but the former origin appears not improbable. Considerable alterations in the composition of the bile may be induced experimentally by modifying normal metabolic processes, but there is as yet no satisfactory evidence that cleavage products arise in this manner.

The decomposition of the bile, which is referable directly or more remotely to the activity of bacteria, may be presumed to alter profoundly the conditions upon which the presence of certain constituents (cholesterin, lime salts) of gall-stones largely depends and may thus have important bearings upon the problem of precipitation. A scientific discussion of this influence is at present not possible.

*Influence of Reaction.*—The opinion has already been expressed that variations in the reaction of the bile do not ordinarily play a leading rôle in determining the precipitation of the constituents of gall-stones but some further discussion of this point will not be amiss.

Very carefully conducted experiments made by Dr. E. K. Dunham* on the influence of the growth of the typhoid organism and the *Bacillus coli* on diluted sterile human bile indicated that even a considerable growth of these organisms after many days occasions only the slightest change in reaction, in the direction of acidity. It is possible that more pronounced acid production would be observed if the period of growth of these organisms had been retarded.†

It has been stated that the presence of free alkali in the bile is favorable to the separation of bilirubincalcium. We do not know, however, that an alkaline reaction is essential to this separation. An acid reaction would probably be inconsistent with the precipitation of bilirubincalcium.

Whether the production of alkali (ammonia acids) by the bacteria concerned in the establishment of cholecystitis is really a factor in the precipitation of bilirubincalcium is still uncertain.

From what has been said it appears conceivable that alterations in the reaction of the bile should exert some influence upon the precipitation of cholesterin and bilirubincalcium and that changes from an acid to an alkaline reaction or the reverse should have some significance for the stratification so often observed in gall-stones. Nevertheless the variations of cholelithiasis biles from the normal reactions are probably only very slight and the idea that the constituents of gall-stones are precipitated in consequence of alterations in reaction cannot be said to rest on a firm basis.

*Effect of Concentration.*—Mere concentration of canine and human bile appears to have very little influence upon the separation of bilirubincalcium, so long as bacterial decomposition is excluded. Bilirubin may, however, separate if the concentration be considerable. Mr. Rettger's experiments indicate that dog's bile is not usually saturated with cholesterin and that some concentration of the bile is possible without occasioning precipitation. The fact that the bile salts are concentrated *pari passu* with the concentration in cholesterin may help to explain the absence of cholesterin separation even after considerable concentration of the bile. Apparently the chief effect of mere concentration of the bile is to increase the liability to separation of bilirubin, but the question has not been fully worked out.

*Presence of Proteids.*—Steinmann found that egg albumin is capable of throwing calcium carbonate out of solution of calcium salts, and Naunyn showed that this mixture of proteids throws bilirubincalcium out of solution under certain conditions. Nannyn expresses the opinion that proteid substances may play a considerable rôle in determining bilirubincalcium separation from the human bile and thus have much to do with the formation of concretions. During cholecystitis various proteids make their escape from the epithelial cells of the gall-bladder into the bile, but we are still in ignorance as to the part they actually play in the production of calculi.*

*Presence of Foreign Bodies.*—Reference has already been made to the comparatively small influence of foreign bodies in causing cholelithiasis. It sometimes happens that the human gall-bladder contains a piece of silk ligature or a bit of metallic nature which has become incrusted with calcium salts. That the action of micro-organisms is not essential to such incrustation is evident from the experiment of Myake, in which a

*Note by Dr. Dunham.*—Experiments to determine changes in reaction of nutrient media containing bile were made as follows: Human bile was mixed with five times its volume of distilled water containing 1 per cent. of Witte's pepton and one-half per cent. of table salt, and the mixture filtered. In one experiment, this filtrate was placed in fermentation tubes and sterilized, by the intermittent method, in an Arnold Sterilizer. In another experiment the sterilization was accomplished by filtration through a Berkefeld filter. The fermentation tubes were inoculated with the colon bacillus or typhoid bacillus and kept in the incubator at 37° for from seven to ten days; blank tubes being kept under the same conditions as controls. After these intervals cultures were made from the fermentation tubes and then their contents titrated with a tenth-normal hydrate solution. In all cases the control tubes were sterile, and the other tubes were shown to contain pure cultures of the bacteria with which they had been inoculated. The appearance of the media in the fermentation tubes and in shake-gelatine cultures from them showed that a moderately abundant growth had taken place in the inoculated fermentation tubes.

Five cubic centimeters of the media in the fermentation tubes were diluted with distilled water to 200 c.c., and this diluted solution, which had a light green color, was titrated, phenolphthalein being used as an indicator. The amount of decinormal sodium hydrate solution required to effect a distinct, though faint, change of color in the diluted medium was noted, and then the standard alkaline solution added until a drop no longer caused a change of color at the point of introduction. There were no marked differences discovered between the reactions of the media in the control tubes and those in which a growth of the colon bacillus or the typhoid bacillus had extended over a period of seven to ten days. The differences noted were not greater than 0.1 c.c. of the decinormal alkali. Such a difference might be due to variations in the amount of evaporation in the different fermentation tubes or to errors in titration owing to the green color of the solution: It appears certain that no alkali is produced, and that, if there is any increase in the acidity of the media, it is very slight.

†*Note.*—Cholesterin is less soluble in an acid than in a neutral or alkaline bile and it is conceivable that even slight changes in the reaction of the bile may influence the separation of cholesterin crystals from a supersaturated solution. When cholesterin has once begun to be deposited about the nucleus of a future gall-stone it is not difficult to understand why the process continues, until cholesterin is no longer produced in such excess, through the desquamation of cells, that it suffices to keep the bile supersaturated. The real problem is to explain the first crystalline deposit of cholesterin.

It is well known that small masses of altered epithelium and bacteria are commonly found in the centers of cholesterin stones and it occurs to one that this fact may perhaps be related to the production of acid by the bacteria which often cluster so abundantly about epithelial remains. The multiplication of these organisms with the production of acid might perhaps determine the precipitation of cholesterin at the limited surfaces where the acid is liberated and where owing to the slowness of diffusion the ions might be presumed to exist in greater concentration than elsewhere in the bile. The process of crystalline deposition once begun the maintenance of an acid reaction at the point of deposit would hardly remain a necessity for further accretion to the young calculus, since according to a well recognized physical law crystalline deposits readily occur where similar crystals already exist.

In the alkaline fermentation of the urine we have a condition which furnishes us with a legitimate analogy. Here, as is well known, we often find deposits of crystalline phosphates in the mucus. But it is in the mucus that the alkali-forming bacteria are growing most energetically, and it cannot be doubted that the early deposition of crystals in the mucus (before their appearance elsewhere and before the entire volume of the urine is distinctly alkaline) depends on the focal liberation of diffusible alkali.

Whether cholesterin is ever precipitated in crystalline form when the bile reacts alkaline to phenolphthalein is at present unknown.

*Normal canine bile is capable of dissolving considerable quantities of Merck's mucin prepared from bile. May not an increase in the mucin of the human bile have some influence on the separation of bilirubincalcium?

silk thread was incrusted with lime salts, although the bile was sterile. Neither bilirubin nor cholesterin could be detected in the incrustation. At the present time there is no evidence that either cholesterin or bilirubincalcium ever separates merely because of the presence of a sterile foreign body in the gall-bladder. On the other hand there is much reason to believe that certain foreign bodies, such as masses of bacteria, and masses of epithelial cells, may act as the nidus for a gall-stone in the presence of a bacterial cholecystitis.

*Influence of Agglutination.*—Harvey Cushing* has called attention to the fact that in typhoid fever there may be an active agglutinative serum reaction toward both *Bacillus typhosus* and the colon bacillus isolated from the gall-bladder. The bile may share the agglutinative properties of the serum. Richardson† has examined at autopsy the bile of fatal cases of typhoid fever and found large clumps of bacilli in five out of six cases. It is possible that bacilli agglutinated in large clumps by agglutinations present in the bile are more likely to form the nidus for stone formation than individual unclumped bacilli or smaller clumps of bacilli, but definite information on this point is lacking. It is also uncertain whether a large clump of living bacteria offer a better starting point for the production of a gall-stone than an epithelial fragment or cell of equal size. The possibility already mentioned, that living bacteria may influence by their products the reaction of the bile, especially at the seat of their production, and thus facilitate the separation of cholesterin or of bilirubincalcium is perhaps worthy of receiving serious consideration in connection with the phenomena of agglutination.‡

*Time Required for Gall-stone Formation.*—Until within very recent years there was no information as to the time required for the production of a human gall-stone. This arose from three circumstances. First, gall-stones may lie for an indefinite period in the gall-bladder without causing symptoms. Hence ordinary clinical observation could not furnish the needed light. Secondly, the size, number, consistence and chemical characters of gall-stones afford no certain data as to their age. Lastly, no one had succeeded in experimentally inducing true gall-stone production. The work of Gilbert and Mignot, already described, has shown that under suitable conditions true gall-stones may be experimentally induced in the course of three to six months. We cannot without further information assume that the same period suffices for the production of human stones, but these experimental results are strongly suggestive of the possibility of rapid calculus production in man. An observation made by Hansemann makes it probable that a human gall-stone may attain a moderate size in the course of seven months.* The case in question is not quite conclusive, because although the stone was an ordinary mixed cholesterin and bilirubincalcium calculus, it probably had an extracystic origin in the duodenum of a patient who had undergone a gastro-enterostomy. The absence of an acid gastric juice was apparently an important element in permitting the production of the stone. Homans† has reported an instance in which stone-formation recurred in not more than one year and eight months and Kelve‡ records a case in which the period of reformation was probably less than a year and a half.

Although positive evidence is still wanting we are justified in regarding it as probable that gall-stones may form in the human gall-bladder in the course of three or four months, when the conditions are especially favorable. Hence, when an early operation for cholelithiasis is undertaken the possibility of an early recurrence cannot be left out of mind, as the gall-bladder is liable to be left in an infected state.

*Paths by which the Bacteria Enter the Gall-bladder.*—There are three paths by which microorganisms may gain access to the liver and through the liver to the contents of the gall-bladder: (1) From bacterial foci which discharge into the general circulation; (2) by the passage of bacteria into the common bile duct from the duodenum; (3) by the passage of bacteria from the intestine into the portal circulation. The first path is probably frequently followed by the bacteria that set up the cholecystitis which is responsible for making calculi. The second path at first sight seems the most important and natural one for cystic infection. Yet we do not know under precisely what conditions infection follows this route. In health the duodenum contains few bacteria and these are not of the varieties responsible for the cholecystitis that lead to cholelithiasis. In gastroduodenitis and duodenitis streptococci are sometimes abundant in the duodenum and may perhaps find their way to the gall-bladder. Possibly also in the course of other digestive disturbances colon bacilli find their way along the biliary ducts to the gall-bladder.

There is some reason to believe that the most frequent route for infective agents is the portal circulation. This view has been especially emphasized by Dr. Lartigau,§ of New York, who induced inflammation of the intestine of dogs by means of corrosive sublimate and other irritants. The animals thus prepared were fed (patho-

‡The agglutinative properties of the bile have been recently investigated by Arnold Cantani, Jr. He finds that the bile of animals immunized against typhoid, colon or influenza bacilli possess a considerable agglutinative activity for these organisms. This activity is, however, distinctly less marked than that possessed by the blood serum. (Ueber die agglutinirenden Eigenschaften der Galle. §New York Academy of Medicine, Dec., 1902.

genic) bacteria which were soon found in the bile. In some instances the cystic duct, in others the common duct, was ligated previous to the feeding with bacteria. Hence infection must have occurred through the intestinal mucous membrane, doubtless at the point of injury.

Dissenting voices have been raised against the doctrine that biliary infection occurs through the portal vein. Thus in a recent paper Carmichael* states that he injected, in separate experiments, typhoid bacilli, *Bacillus coli communis* and *Streptococci* into the portal circulation of rabbits without being able to recover bacteria from the bile. He considers that these experiments not only support the view that the liver destroys the micro-organisms that reach it but render improbable the occurrence of biliary infection by way of the intestine and portal circulation. If, however, we take into consideration the positive results obtained by Blachstein,† Fütterer‡ and others there can remain no doubt that the intravenous injection of *Bacillus typhosus* and *Bacillus coli communis* is very often followed by the appearance of the injected organisms in the bile. It is true that in these experiments the bacteria were put into the systemic circulation and may have reached the gall-bladder through the cystic artery, without having first traversed the liver, but this appears unlikely. Dr. Welch§ states his belief that Blachstein's inoculations were very often followed by negative results as regards infection of the bile. These negative results are probably referable mainly to the bactericidal powers of the liver cells. The negative results obtained by Carmichael cannot therefore be taken as proof that biliary infection does not arise by way of the portal circulation. A consideration of the evidence at present available makes it extremely probable that the bile may be infected by way of the portal system, despite the bactericidal action of the liver cells. This is true not only of experimental infections in animals, but also of human biliary infection with the organisms of typhoid fever, and the *Bacillus coli communis*. How often infection of the bile arises in consequence of ulcerative lesions in the intestinal tract is not yet clear, but it is certain that such lesions must greatly influence the liability to biliary infection. As yet, however, it is impossible to say with certainty whether the portal system or the direct duodenal path is the more frequent route of biliary infection in man.

*Do Gall-stones Originate Independently of Infection of the Bile Passages?*—The facts that have been reviewed clearly show that through the local action of bacteria upon the walls of the gall-bladder (or bile passages) there may be created all the conditions essential for the production of gall-stones. The experimental formation of real calculi makes it safe to conclude that derangements in general metabolism are not essential factors in the process of production. This is, however, no evidence that disturbances of metabolism which modify the composition of the bile, may not under certain conditions play an important part in bringing on cholelithiasis. There are many French and English writers who hold that constitutional states attended with metabolic disorders are a common cause of gall-stone formation. It is worth while to examine the foundation on which this view rests.

*Constitutional Influences Modifying the Composition of the Bile.*—It is surprising to find how little satisfactory information exists as to the influence of different kinds of dietaries on the composition of the bile. Paton and Balfour* found through observations on a woman with a biliary fistula that the amount of solids in the bile rose with the amount of nitrogen excreted by the urine. Brockbank† looks on these observations as evidence that more bile salts are produced from a nitrogenous diet than from one poor in nitrogen. Admitting this inference to be sound one would be led to the conclusion that persons on a diet rich in nitrogen make bile capable of holding in solution more cholesterin than persons who live on meager nitrogenous rations. Whether there is actually a greater liability to gall-stones among those who consume little nitrogen is not conclusively shown by any statistics bearing on this point. I cannot believe that variations in the percentage of bile salts are of great importance in determining the incidence of cholelithiasis, for the reason that the great factor in the formation of cholesterin containing stones is the local condition of the gall-bladder. In other words a cholecystitis leads to the local presence of so much cholesterin that the quantity of bile salts in the bile cannot greatly influence the ultimate deposition of cholesterin.‡ There is no reason to think that the percentage of bile-salts in the bile exerts an influence on other biliary constituents than cholesterin.

Whether an increase in the cholesterin of the blood, from constitutional causes, ever markedly modifies the amount of cholesterin in the bile is a question that cannot now be answered. Fischer reports a case of diabetes with lipemia and cholesteremia in which the blood held at least 0.478 per cent. of cholesterin, a quantity greatly above the normal average.§ The observation is of interest as indicating the possibility of a marked cholesteremia in a constitutional disease, but there is no certainty that even so great an excess of cholesterin in the blood leads to a significant excess in the cystic bile.

Further studies of the relationship between the

§Hoppe-Seyler found from 0.02 to 0.06 per cent. of cholesterin in the plasma and serum.

cholesterin of the blood and of the bile are much to be desired.*

*Influence of Excessive Feeding of Fat.*—Gall-stones sometimes contain a considerable percentage of fat, which may be present chiefly as a compound of stearic acid.† As the origin of this acid is obscure it was determined to make some observations with a view to learning whether the ingestion of large quantities of fat has any influence on the fat content of the bile, as has been stated by Naunyn. These observations had an unexpected outcome.

Two dogs were fed on boiled beef fat and an extremely small amount of boiled meat. During twelve weeks one dog (weighing about 32 pounds) was induced to eat from one-half to one pound of fat daily. During the last two weeks of the experiment he received potatoes mixed with fat. At autopsy the subcutaneous and omental fat was found to be extremely abundant. The liver was very markedly fatty. The bile was normal in quantity, color, consistence and reaction (faintly alkaline to litmus) but contained an abundant sediment of dark brown particles about the size of large grains of sand. These little masses were found to consist of pigmented, highly refractive hyaline material mixed with the débris of degenerating epithelial cells, portions of which were stained readily by osmic acid. No cholesterin could be detected in these particles; certainly none was present in crystalline form.‡

A second dog (about 19 pounds) was fed for nine weeks in the manner just described. For 3 weeks he consumed nearly one-half pound of fat per day. Then for a week he refused to eat. During the last two weeks of the experiment the fat was mixed with potato and was voraciously eaten. The gall-bladder contained a little bile of normal consistence, color and reaction (slightly alkaline). Affixed to the base of the gall-bladder was a small, black spherical concretion (about 4 mm. in diameter), of somewhat firm consistence. Near it lay numerous small detached irregularly shaped black masses of apparently the same material. Microscopical examination showed the concretion and the separate masses to consist of deeply pigmented, highly refractive hyaline material. No crystals of cholesterin were detected. The mucosa near the adherent body was considerably thickened and presented numerous small translucent miliary projections.§ The mucosa for a short distance about the adherent body was covered by a gelatinous layer of great transparency from 1 to 2 mm. in thickness, apparently consisting of mucinous material.*

Sections made through the gall-bladder and the attached intracystic body showed the "concretion" to be made of a group of glands greatly dilated by what is probably an accumulation of partially transformed mucus, grown firm from inspissation. A fuller description of this body will be given when the results of other fat feeding experiments are described.

These observations are of some interest on account of their suggestiveness. I have examined the gall-bladders of a large number of meat-fed dogs without having ever observed a sediment like that found in our first dog or an attached body like that discovered in our second. Whatever may be the origin of these pathological conditions it is improbable that they are dependent on infection of the gall-bladder. Positive evidence on this point is unfortunately wanting, as I carelessly omitted to make cultures from the bile. Nevertheless it seems most likely that the changes observed are of diathetic rather than local origin.

Two leading questions are raised by these experiments: First, do the glandular alterations noted in the gall-bladder depend on the pathological conditions of fat metabolism, and secondly, do similar glandular accumulations occur in the human subject and sometimes form the beginnings of true gall-stones? An answer to these questions may reasonably be expected from additional experimental observations and from histological studies of the human gall-bladder.†

*Influence of Gout, Arteriosclerosis and Diabetes.*—Some writers have assumed the existence of a close connection between gout and gall-stones and various hypothetical‡ reasons have been advanced to explain the alleged connection. I have been unable to find any substantial evidence in favor of this relationship between cholelithiasis and gout. In the 179 Presbyterian Hospital cases which Dr. Williams has analyzed for me there is no instance in which a history of gout was noted, although some form of rheumatism existed in 20 of these patients. This showing is thus extremely different from foreign statistics like those of Lenac, where gout was present in 95 out of 166 cases of cholelithiasis. That gout and gall-stones should be often associated in countries where both diseases are common is not surprising and the fact does not in itself imply any etiological relationship.

*As red blood cells contain considerable cholesterni, pathological processes attended with excessive hemolysis might be expected to raise the cholesterin of the blood, but I am not aware of any observations bearing on this point.

†It is said that gall-stones occasionally contain as much as 16 or 17 per cent. of stearic acid. In a series of variegated gall-stones examined for me by Mr. Rettger stearic acid was positively detected in no instance, although in one case it may have been present in very small amount.

‡Analysis of the bile from this dog gave the following results:

| | |
|---|---|
| Cholesterin | .360 per cent. |
| Calcium oxide | .09 per cent. |
| Ethereal extract, not including soaps, but consisting of neutral fat, cholesterin and lethicin | .97 per cent. |
| Solids of bile | 20.29 per cent. |

Although the cholesterin residue was somewhat oily and contributed to give a high weight it seems clear that the cholesterin in the bile was increased considerably above the normal.

§The miliary projections were seen on histological examination to consist of groups of simple glands whose lumina were considerably distended with mucus.

*Analysis of the bile from this dog gave the following results:

| | |
|---|---|
| Ethereal residue after saponifying (including neutral fat, fatty acids, soaps and cholesterin) | 3.39 per cent. |
| Cholesterin found | .213 per cent. |
| Calcium oxide | .120 per cent. |
| Solids of bile | 22.09 per cent. |

Cholesterin figure is somewhat high on account of admixture of oily substance.

†I believe there is much to be learned about the pathology of the bile in its relation to cholelithiasis from systematic chemical and histological studies of the sediments so often found in human gall-bladders (even where autopsies are made early) and from histological studies of the mucosa of the dependent parts.

‡See Brockbank, loc. cit., p. 85.

As both arteriosclerosis and gall-stone disease increase in frequency with advancing years we cannot wonder that they should be often observed together in the second half of life. The statistical reports to which I have had access do not certainly establish a special etiological relationship. It is noteworthy that among Dr. Thacher's Presbyterian Hospital cases some form of arteriosclerosis (coronary disease or alterations of the aorta) existed in 80.4 per cent. But in order to give these figures any special significance it would be necessary to show that calculi are distinctly more common in arteriosclerotic persons than in persons of comparable ages dying from all other forms of disease. A study of Dr. Thacher's records from this point of view has been commenced by Dr. Williams but is at present not completed.

It has been often claimed that there is a close connection between diabetes and biliary calculi but a critical examination of the evidence does not sustain this contention. On the contrary it appears to me that gall-stones and diabetes are but rarely associated. Dr. Williams says that Kundrat observed cholelithiasis only once in 92 autopsies on diabetic patients. Of Dr. Thacher's 179 cases two died of diabetes.

The fact that gall-stones and diabetes are not more frequently associated has one important bearing on the theory of gall-stone formation. Bouchard, who has been a strong advocate of the constitutional hypothesis of cholelithiasis attributed the alleged relationship between the two diseases to the well known acid production of diabetes. He also believed that pathological acid production in other conditions than diabetes is a factor in causing gall-stone formation. If an acid intoxication ever exerts an influence on gall-stone formation, it should certainly make itself felt in diabetes, where very large quantities of pathological acids are often produced. Yet there is not reliable statistical evidence of this supposed effect; and it must be said that one would hardly expect the acid intoxication of diabetes to influence the reaction of the bile, as the pathological acid in the blood is so promptly neutralized by ammonia and other bases. There is thus no reason for supposing that free acid ever reaches the bile from the blood. This fact has not been sufficiently considered by those who favor the doctrine that acid intoxications have an influence on gall-stone production.

It is plain from what has been said that there is at present no unequivocal evidence that gall-stones arise from constitutional derangements unconnected with micro-organic invasions of the gall-bladder. On the other hand it is certain that the cholesterin of the bile can be considerably increased by local irritants unconnected with infection and it is likely that the requisite local conditions for such increase sometimes arise through purely metabolic disorders. While gall-stones are commonly the result of local infections we should carefully guard against the conclusion that they can never have a diathetic origin. It is at least highly probable that diathetic conditions are capable of so altering the composition of the bile as to materially favor the production of calculi in the presence of suitable local bacterial activities.

*Medical Treatment of Gall-stones.*—Few facts have as yet emerged from the nebulous region of gall-stone therapeutics. We have learned that the surgeon is far more successful than the physician in the treatment of established cholelithiasis. We have learned also that certainly most of the drugs to which cholagogue virtues were once attributed are really undeserving of confidence. The bile salts and possibly the salicylates possess cholagogue properties, but whether these can be turned to account to bring about the solution of a gall-stone must be considered very doubtful. It is certain that through the free use of fat in the dietary the percentage of fat in the bile may be increased above the average but we do not know whether the increase is ever so great as to cause a marked solvent action on the cholesterin of the gall-stones. Such an action appears to me improbable. Other constituents than cholesterin are insoluble in fat. The experimental results which we have obtained from prolonged feeding of fat raise the question whether it is really wise to give patients a rich oleaginous diet, especially in those substances where there is obesity and an inactive habit of life. Restriction both in fats and carbohydrates seems the more rational course and with this there should be free muscular exertion when this is practicable.

It seems probable that in future physicians who treat patients with gall-stones will direct their attention largely to measures designed to favor the subsidence of cholecystitis. How much it is possible to influence such a condition we cannot positively say. Hygienic influences that raise the general bactericidal powers of the cells presumably have a beneficial effect upon cholecystitis of infective origin. The value of antiseptics is a matter which future studies will have to decide but it is not unreasonable to hope that some bactericidal effects will be shown to result from the use of certain antiseptics, which like benzoic acid may enter the bile.

*Statistical Note.*—Dr. John S. Thacher, of the Presbyterian Hospital, was so kind as to place at my disposal the records of autopsies made there, and Dr. Lindsay Williams undertook to analyze these records with reference to their bearing on the incidence and etiology of gall-stones. Some of the results of Dr. Williams' analysis are of sufficient interest to incorporate in this report on the etiology of biliary calculi.

Among 2,371 autopsies gall-stones were found in the gall-bladder 179 times (7.6 per cent.). Of these gall-stone subjects 99 were females, 80 were males. But as the percentage of males among the entire number of patients subjected to autopsy was 65.5, the incidence of cholelithiasis was really a little more than twice as great in females as in males. The distribution of the cases as regards age was as follows:

| Males. | | Females. | |
|---|---|---|---|
| 10 years | 1 | 20 to 30 years | 7 |
| 10 to 20 years | 0 | 30 to 40 years | 19 |
| 20 to 30 years | 3 | 40 to 50 years | 19 |
| 30 to 40 years | 3 | 50 to 60 years | 20 |
| 40 to 50 years | 15 | Over 60 years | 23 |
| 50 to 60 years | 25 | Unknown years | 11 |
| Over 60 years | 29 | | 99 |
| Unknown years | 4 | | |
| | 80 | | |

Of 50 women about whom the facts were ascertainable 70 per cent. had borne children. The adipose was described as "fair," "considerable" or "abundant" in 113, as "scant" or "poor" in 59.*

No satisfactory information in regard to the chemical character of the gall-stones was reached in the majority of instances. In 32 cases the stones were single. In several instances large numbers of calculi were present; once there were more than 100, once 267, once the number exceeded 1,000. Very frequently there were from 12 to 40 stones in the gall-bladder. Frequently also there were present from 2 to 12 stones.

As to family history there is nothing notable to record, except that a family history of tuberculosis was obtained in 12 instances. As to personal history the following points were noted: Typhoid fever was present in 5 cases, but this of course gives no indication as to the number of stones of typhoid origin. Tuberculosis could be detected clinically in 7 patients and was several times found at autopsy, when it had not been recognized during life. Syphilis existed in 6 cases. A history of gall-stones or colic or obstructive jaundice was present in only 9 cases. In 33 cases the use of alcohol was admitted. In 20 cases there was a history of rheumatism in some form. No case of gout was known to exist, nor could a history of lacing be obtained in any case.

In 11 cases no note was made of the condition of the liver. In 50 cases this organ was normal or nearly normal (gross appearances). In 56 cases the liver was congested or nutmeg. In some of these the liver was also fatty or cirrhotic; the liver was markedly fatty in 28 cases, cirrhotic in 20. All but six of the 28 cases of fatty liver occurred in women, a large proportion of whom were over forty years of age. The preponderance of women with both gall-stones and fatty liver over men is therefore about twice as great as the preponderance of women over men in the entire series of cases. New growths were present in the liver in 9 cases, abscess existed in 6 cases.

Of the 87 cases in which suitable data exist as to the condition of the arteries, arteriosclerosis was present in 70 (80.4 per cent. of these 87 cases). In these cases alterations were found either in the coronaries or in the aorta or in both situations.

The total number of deaths referable directly to gall-stones or their sequelæ was 11 (6.1 per cent.). This low percentage is probably not referable to any considerable extent to the results of operative interference, as many of the cases occurred before the days of highly accurate diagnosis and early operation.

Perhaps the most striking thing about this analysis by Dr. Williams (to whom I am much indebted) is the large proportion of cholelithiasis patients who showed arteriosclerotic changes. It is not yet apparent, however, that this frequent association possesses any special etiological significance, as it is not clear that similar lesions in persons without gall-stones are not equally frequent at autopsies on patients of the same age, sex and habits of life. As the point is one of some interest a statistical comparison is now being made with a view to determining whether the high proportion of arteriosclerotic lesions in gall-stone cases has any etiological meaning.

I wish to express my sense of obligation to Dr. A. J. Wakeman and Dr. Helen Baldwin for their essential contributions to this paper, and to Dr. J. S. Thacher and Dr. Lindsay Williams for facts relating to statistical questions. I desire also to thank Dr. J. Edgar Welch for his zeal in obtaining for me the autopsy material on which Dr. Baldwin's analytical work is based.

*In some instances the body was described as emaciated.

## THE PATHOLOGY AND TREATMENT OF TARDY POSTOPERATIVE INTESTINAL OBSTRUCTION WITH A REPORT OF CASES.

BY ELLSWORTH ELIOT, JR., M.D.,
OF NEW YORK.

Acute obstruction following laparotomy is not a rare occurrence. It is most frequently the result of paralysis of peristaltic activity from a spreading or septic peritonitis; it occurs less frequently after laparotomy for a non-purulent condition, even though no infectious material has been introduced at the time of operation. In this latter group of cases, the obstruction is usually of a mechanical nature and is due to the angular adhesion of one or more loops of intestine to the parietal peritoneum, to each other or to the stump of some recently ligated pedicle of omentum or ligated base of tumor to a possible volvulus or to the protrusion of a coil of intestine through some accidental orifice in the mesentery or other peritoneal structure.

In all of these conditions, the symptoms indicating obstruction develop shortly after the operation and usually before satisfactory restoration of the intestinal function has taken place. On the other hand, "tardy" intestinal obstruction, following operation, refers to those cases in which an interval of weeks, months or even years elapses before the symptoms of obstruction appear—an interval, in which the patient enjoys excellent health and in which there is no irregularity in the movement of the bowel. In this group of cases the cause of the obstruction is always of a mechanical nature, the lumen of the intestine being narrowed by the contraction of a circumferential cicatrix within its wall or by the constriction of a

band without, beneath which the intestine has accidentally passed and subsequent extrication has proved impossible. In other cases, the stricture is due to the progressive kinking of a segment of intestine from the contraction of adhesions of organized connective tissue, joining together at an angle those loops of which the segment is composed. In many cases several of these conditions coexist.

Apart from the particular form of constriction, there is little variety in the lesion. The gross changes comprise one or more bands of connective tissue, in the formation of which the great omentum is a very frequent and important factor. These bands are attached to some fixed point on the parietal peritoneum or to some fixed or movable viscus. In this way it forms the portion of the boundary of a small aperture beneath which a loop of intestine becomes imprisoned and subjected to such constriction, that, in the absence of relief, necrosis is inevitable.

The adhesions between adjacent loops of intestine are formed of similar tissue of so firm a character, that the mass of intestine can be disentangled only with considerable difficulty and only by the generous use of forceps and scissors.

Stricture due to the constriction of a circumferential scar in the wall of the intestine is of the simple non-malignant variety and presents the usual features of that condition. To the outer surface of the stricture, the omentum and one or more loops of intestine are usually adherent.

Other pathological changes may be associated with those directly responsible for the obstruction; thus, adhesions and bands in more or less remote parts of the abdominal cavity are not infrequent and, in addition, the lesions, such as those of a chronic tuberculous peritonitis for the relief of which the original laparotomy was performed, may coexist.

Without interference, the constriction leads to necrosis or perforation of the wall of the affected gut with subsequent spreading peritonitis, a condition so well recognized as to require no further description.

The symptoms indicating obstruction develop either slowly or gradually: in the former group of cases, occasional attacks of constipation which are not sufficiently marked to attract the attention of the patient, with or without colicky pain, occur irregularly during a period of several months prior to the final attack of obstruction; in the latter group, symptoms indicating serious obstruction appear without warning or premonition of any kind: in both, the obstruction proper runs a rapid course. The treatment is prophylactic, in that by observing certain precautions and by careful attention to detail and technic both during and directly after the primary operation, the danger of the formation of permanent adhesions is very largely minimized. The treatment of the attack of the obstruction proper does not differ materially from the treatment of acute obstruction from any cause.

Prophylactic measures at the time of the original laparotomy include the careful exclusion of any kind of mechanical, thermal or chemical irritation from the contents of the abdomen. Thus, the utmost gentleness should be observed in the necessary manipulation of intestine and every precaution taken to avert the accidental catching of a loop with the edge of a retractor. The use of too hot saline fluid or of germicidal solutions containing some chemically irritant or caustic ingredient such as the bichloride of mercury, for purpose of irrigation, damages the visceral peritoneum and should be carefully avoided.

All ligatures, by acting as foreign bodes, are sources of mechanical irritation and should therefore not be needlessly applied; thus, many adhesions, the result of previous localized peritonitis may be divided without fear of hemorrhage; on the other hand, the pedicles of tumors or bands connecting these with the adjacent parietal peritoneum frequently contain large blood-vessels, requiring ligature, the irritant effect of which, however, can be diminished by the use of catgut rather than of silk. Another frequent cause in the production of chronic peritoneal adhesions is the presence of denuded stumps such as those of an amputated appendix or of the uterus and broad ligaments after a supravaginal hysterectomy. To obviate as far as possible band formation from this cause, the surgeon endeavors, prior to the closure of the abdomen, to cover all stumps with a smooth peritoneal investment. In the amputated appendix, this is accomplished by a purse-string suture around its base; in hysterectomy, by covering the uterine stump with a flap of peritoneum and by drawing together with Lembert sutures the parietal peritoneum on either side of the ligated broad ligament. In addition to these precautions, lines of suture may be covered, when feasible, with omentum, the adhesions which develop between such suture lines and omentum being preferable to angular adhesions of loops of intestine to each other.

Unfortunately, however, in certain laparotomies, the separation of extensive adhesions, involving the parietal peritoneum, the mesentery, and the hollow viscera exposes denuded areas so large that their investment with peritoneum proves impossible. In these cases an effort may be made to diminish the almost certain probability of band formation by covering the exposed area with a segment of very thin rubber tissue or of Cargyle membrane. Sufficient time has not yet elapsed to permit of an accurate estimate of the efficacy of this procedure in the human subject. The writer has observed in several instances, parietal displacement of pieces of Cargyle membrane from the wall of intestine due to the friction associated with the return of the affected loop into the abdominal cavity. Such displacement may be prevented in the case of rubber tissue by the passage of several sutures between it and the edge of the denuded area.

The management of drainage is an all important factor. The use of a drain in almost all laparotomies for abscess formation is indispensable; its

presence, nevertheless, is disadvantageous in that it favors band formation. Occasional exceptions are, however, noted from time to time in those cases in which, a second laparotomy being necessary, the adhesions observed at the time of the primary operation have either become insignificant or have entirely disappeared.

Notwithstanding occasional immunity from this danger, therefore, band formation, after the use of drains to such an extent as to prove a future source of trouble, is a distinct probability. The risk so incurred may be minimized by using as small an amount of drainage material as is consistent with the patient's safety and in the event of a capillary gauze drain, by enveloping the same in a cylinder or sheath of sterilized rubber tissue.

Furthermore, the early change of the drain with subsequent diminution of its bulk when it must be replaced, and, in certain cases, its early complete removal render the formation of permanent adhesions less likely.

The immediate postoperative treatment consists in establishing at the earliest possible moment, normal or preferably exaggerated peristaltic activity. During the first twenty-four hours, when the stomach is in an unsettled condition, the restoration of that function is favored by the use of rectal enemas of warm saline solution with or without turpentine and, in cases of persistent vomiting, by lavage. As soon as the nausea and vomiting subside, small doses of calomel and salts should be administered and movements favored by high turpentine injections. These measures avert to a certain extent not only the adhesion of intestinal loops but by the removal of all fermenting material, the development of adhesions from possible chemical irritation of toxic substances as they are absorbed by the intestinal wall, is very largely prevented.

The formation of adhesions is still further probably decreased by frequent changes in the position of the patient. This can preferably be accomplished by alternately raising and lowering the head or foot or sides of the bed. In this way, without discomfort to the patient the mobile contents of the abdomen may be directed to different parts of the cavity through the action of gravity.

These various measures are not cited as a part of the routine treatment of every laparotomy, but only when, after an extensive or infectious peritonitis, or after operations involving suture of the intestinal loops or after operation for the relief of obstruction due to bands subsequent band formation is to be apprehended.

The actual treatment of the obstruction proper does not differ essentially from the treatment of obstruction from any cause. Early laparotomy, the ligation and removal of constricting bands, the disentanglement of adherent intestine with resection (in those cases in which the loops are so firmly bound together that their separation is impossible, or in those cases in which the affected intestine has become necrotic), subsequent closure of the abdomen with or without drainage, together with the adoption of those measures already described, for the prevention, if possible, of subsequent adhesions, comprise the general routine treatment in these cases.

*Case I.*—Laparotomy for gangrenous appendicitis, complicated with general septic peritonitis; recovery. Acute obstruction seven weeks later; operation on the fifth day, death.

G. L., aged twenty years. With the exception of two attacks of catarrhal appendicitis during the past three years, patient has always enjoyed excellent health. About ten days before the patient was seen by the writer, the present attack began, the invasion being marked by severe pain, at first in the vicinity of the umbilicus, afterward referred to the right iliac fossa. During the first forty-eight hours there was vomiting and constipation, the latter yielding to catharsis. The pulse was at no time over 90 nor the temperature over 100°F. An examination by the attending physician showed general rigidity of the abdomen, most pronounced in the right lower quadrant, and tenderness on pressure. These symptoms continued for about one week, when the vomiting which had previously subsided, recurred and became fecal, the constipation absolute with the pulse increasing gradually to 120 and the temperature to 102° F. At the end of that time, an examination by the writer revealed a firm board-like abdomen without marked distention. There was slight dulness in the lower right quadrant. There was almost complete absence of peristaltic activity. Pulse varied between 130 and 140. General condition was apathetic. Operation under ether.

The appendix was exposed through the usual intermuscular incision. It was deeply situated, overhanging into the cavity of the true pelvis. It was gangrenous and surrounded by a small quantity of very foul smelling pus. There was a perforation near the tip. The cecum and adjacent coils of small intestine were distended, of a dark red color and injected and in places were covered with masses of fibrine. The pelvis and the lower half of the abdominal cavity were irrigated through a secondary incision in the median line below the umbilicus with a warm saline solution. Rubber tube drains, surrounded with iodoform gauze were introduced through both incisions converging into the bottom of the pelvis. Bandage.

For twenty-four hours after the operation, patient's condition was very critical, the pulse ranging as high as 150, and of poor quality. The fecal vomiting ceased immediately, however, and twenty-four hours after, the bowels moved to an enema. The temperature, never higher than 103° F., became normal about the tenth day, the pulse became normal during the third week. Both incisions closed by granulation, and were completely healed at the end of the fifth week.

I am greatly indebted to Dr. James E. Moore for the following notes of the subseqnent obstruction:

About seven weeks after the primary operation

complete constipation developed with symptoms of obstruction. A large dose of calomel and castor oil was immediately vomited. At the end of four days, Dr. Moore was called in consultation by the attending physician and advised immediate operation. The abdomen then had become moderately tense and distended. The peritoneal cavity was opened by an incision along the outer border of the right rectus, disclosing extensive adhesions in every direction, especially in the right lower quadrant. The bowel was greatly distended and rather dark-colored above a band in the upper right quadrant, being collapsed below the point of constriction. With the division of the band, the collapsed portion became gradually distended but only for a short distance when another band was encountered which produced very deep constriction. At least five strong bands and several smaller ones were divided and then the intestine was returned into the abdominal cavity and the wound sutured. The patient's general condition was as good after the operation as before. On the third day the bowels moved after a dose of castor oil and rhubarb, but on the following day patient gradually grew weaker and died.

*Case II.*—P. M., male, aged nine years. On October 24, 1901, about two o'clock in the afternoon, patient was knocked down by a cable car, but did not become unconscious. He complained of pain in the right wrist and hand, the head and the left side of the abdomen. There was pallor and profuse perspiration, and the patient was brought to the hospital in considerable shock. One hour after admission patient vomited green fluid, several attacks occurring in the course of the next two hours. During this time there were several attacks of colicky pain in the abdomen and the condition of shock continued. On examination, the upper two-thirds of the left side of the abdomen was tender and rigid. There was a point of maximum tenderness three inches to the left of the umbilicus. No mass could be detected. The patient lay on the left side and could not move toward the right without great pain. There was some dulness in the right flank. The left thigh was flexed. The pulse was slightly over 130. The rectal temperature about 100° F. Six hours after the accident, the abdominal tenderness had become more marked, and the rigidity had extended over a great segment of the abdominal wall. There was no appreciable improvement of the shock.

Operation eight hours after the accident, under gas and ether. The peritoneal cavity was opened by a 5-inch incision along the outer border of the left rectus above the level of the umbilicus. It contained turbid serum mixed with intestinal contents. A rupture was found in a coil of small intestine, involving one-third of its circumference. It was closed with a Czerny-Lembert suture. The adjacent coils of small intestine were injected and carefully cleansed with hot salt solution, as was also the pelvis which contained a considerable amount of partially digested intestinal matter. Drainage of the pelvis, with partial closure of the abdominal wound.

On the first day after the operation, the pulse was as high as 144, the temperature 102° F. On the third day, the pulse had decreased to 100, and the temperature to 99.5° F. Both became normal on the sixth day. For forty-eight hours after the operation, there was a moderate amount of vomiting. Bowels moved after enema on the second day. The abdominal incision had completely closed by the twenty-sixth day.

On January 16, 1901, the ventral hernia resulting from the primary operation was closed. In the course of the operation, the omentum and loops of intestine were found to be adherent to the edge of the hernial orifice and were separated before the sutures were inserted. The patient made an uneventful recovery.

On May 13, 1901, patient entirely well since last note until four days ago. At that time, after a hearty lunch, severe cramp-like abdominal pain developed, with vomiting and complete constipation. The vomiting at the time of admission to the hospital had become fecal. On examination, there was moderate distention, especially in the upper part of the abdomen. There was slight general rigidity. The vomitus was brown and of a fecal odor. The patient was in a condition of collapse, pulse 120, temperature 100° F.

Operation; gas and ether. The peritoneal cavity was opened by a median incision below the umbilicus. The small intestine was deeply constricted by an omental band near the posterior wall. Above this point, it was greatly distended, and below it was markedly collapsed. The division of the band was not followed by a return of the constricted portion to its original dimensions. It remained deeply indented and its wall seemed thickened from the deposit of connective tissue. No intestinal contents could be forced through. The loops of small intestine directly above and below the stricture were joined by a lateral anastomosis; closure of the abdominal wound. After the operation the temperature rose steadily to 105° F., the pulse to 190, and death took place seven hours afterward.

*Case III.*—K. L., aged forty-six years. This patient was operated on in the Presbyterian Hospital for a fibrocystic tumor of the uterus, October 10, 1899, by Dr. C. K. Briddon. Owing to the density of the adhesions, portions of the cyst wall adherent to the intestine were left behind at the conclusion of the operation. After the insertion of a gauze drain into the pelvis, the remainder of the abdominal incision was closed. There was some suppuration during convalescence.

Patient was readmitted Nov. 1, 1901. Four days before admisssion, after lifting a heavy weight, patient was seized with severe abdominal pain and vomiting which has persisted and become fecal. The constipation has been absolute with the exception of one slight movement following an enema on the first day after the attack began. Since then there has been no discharge of fecal material or flatus. There has been marked

prostration. On examination, the abdomen is prominent especially in the lower right and median zones. There is slight rigidity and tenderness over the tumefaction. Deep palpation under an anesthetic elicits a soft movable and slightly elastic mass. Vaginal and rectal examination negative. On admission, temperature is 100° F., pulse 132, and weak. Patient is in a condition of severe collapse.

Operation under ether. A median incision was made through the old scar and the peritoneal cavity opened. After the sponging away of free bloody fluid the intestine presented in a greatly distended condition and of dark purple color. Just above the ileocecal junction, the small intestine passed beneath a band by which it was tightly constricted, the intestine below being collapsed. The ligation and division of the band was followed by the gradual filling of the intestine below. No other constriction was found. The band seemed to pass from the mesentery over the intestine to the posterior parietal peritoneum and had no connection with any of the pelvic organs. The abdominal cavity was washed out with warm saline solution and closed quickly with sutures through the entire thickness of the wall, as the general condition of the patient was rapidly becoming weaker. Notwithstanding lavage, and infusions, the collapse became more marked and death occurred thirty-six hours after the operation.

*Case IV.*—J. R., aged nine years. Acute obstruction from constriction of a Meckel's diverticulum. Laparotomy. Recovery. Death six months later from some form of obstruction. Admitted to the hospital April 4, 1902. On the day before admission, patient was seized with severe colicky abdominal pains, situated about the umbilicus. There was vomiting from the very beginning, repeated at intervals of fifteen minutes during the night. Two enemata were given without any result and without bringing away any flatus. There was considerable prostration. One week before admission, patient fell, striking abdomen against the edge of a table, the accident being followed by slight pain of short duration.

On examination, the abdomen was generally distended, the left flank projecting slightly more than the right. There was slight tenderness all over but no distinct rigidity. No mass could be felt. There was some dulness in the left flank shifting with the change in the patient's position. Peristalsis could seldom be heard and is very faint. The pulse is 104, respiration 34 and temperature 98.6° F. There was 18,000 leucocytosis.

Operation under ether. The peritoneal cavity was opened by a median incision about 4 inches long beneath the umbilicus. It contained a moderate amount of clear serous fluid. To the right of the median line at a point just above the umbilicus a loop of small intestine had become caught beneath a Meckel's diverticulum which still remained attached to the umbilicus by a firm fibrous cord. This was excised, the diverticulum removed and the stump closed with a catgut suture and thoroughly cauterized. The abdominal cavity was irrigated with a warm saline solution, and the wound closed without drainage.

After the operation there was moderate nausea and vomiting, the latter persisting to the fortieth hour and then yielding to lavage. There was slight abdominal distention during this same period with restlessness, and the pulse varied between 100 and 120, the temperature ranging around 101° F. On the third day after operation a moderate amount of abdominal pain still persisted. This rapidly disappeared when flatus was expelled, and shortly after the bowels moved after enema. Primary union was secured and the remainder of convalescence was uneventful. Six months afterward the patient is said to have died with symptoms of obstruction at some place out of town.

*Case V.*—J. E., male aged 29 years. Admitted to the Presbyterian Hospital June 10, 1902, for chronic intestinal obstruction, which was followed by operation for suppurative appendicitis.

Two years ago patient was operated on in Germany for a suppurative appendicitis with subsequent drainage. Patient was in bed for four months after operation. Since that time the bowels have always been constipated, especially during the past six months, and for the past two weeks patient has been troubled with constant severe pain in and above the upper extremity of the old scar. Two days ago, while lifting a barrel, a swelling the size of a small orange appeared in the cicatrix, which disappeared spontaneously in about ten minutes. Shortly after this there were occasional attacks of vomiting, which persisted up to the time of admission. During the past forty-eight hours there has been no movement of the bowels. On admission the pulse is 80, the temperature 100° F.; patient complains of considerable pain. An enema was followed by a satisfactory movement of the bowels. On examination, there is an old scar about four inches long over the appendix site, between the anterior superior spine and the umbilicus. There is no distention. There is a distinct area of resistance between the upper edge of the scar and the umbilicus, about the size of an egg, and this area is tender on deep pressure. Repeated examinations of the blood never showed a leucocytosis higher than 9,000. The patient was placed in bed, and the diet regulated. The pain, however, and the local resistance persisted, notwithstanding regular movements of the bowels.

Operation on June 20 under ether. The scar was excised by means of an elliptical incision which was deepened along the edge of the cicatricial tissue until the peritoneum was opened. The cecum presented adherent to the parietal peritoneum and from the end of the anterior fibrous band, the stump of the appendix, about an inch in length, extended up and inward to a point on the parietal peritoneum where it was closely adherent. In the aperture so formed a loop of small intestine had become imprisoned and was moderately constricted. The adhesion was divided,

the appendix amputated and the intestine released. The stump of the appendix was buried with a purse string suture of catgut, and the muscular and aponeurotic planes of the abdominal wall were approximated with chromic sutures without drainage. Primary union was secured, the convalescence being uneventful.

*Case VI.*—D. W., aged 22 years. Acute obstruction following a previous internal operation for appendiciticis. Recovery.

On May 16, 1902, patient was operated on by the intermuscular incision for appendicitis. The distal end of the appendix was atrophied and adherent to the iliac fossa. There was no pus. Its removal was accomplished without difficulty and the wound was closed without drainage, primary union being secured and the patient leaving the hospital in three weeks. The stump of the appendix was tied with heavy catgut and cauterized. No attempt was made to bury it with a purse-string suture. Patient remained well until Oct. 1, 1902. In the interval there had been occasional attacks of pain in the right inguinal region intensified by walking and during menstruation. The bowels had remained fairly regular until two days before admission, when patient was seized with severe abdominal pain and persistent vomiting. During this time there has been no movement nor the passage of any flatus. The past few hours the vomiting has become brown, but is not of a fecal odor. On examination, the abdomen is slightly distended throughout. There is tenderness and rigidity, most marked just internal to the old appendix scar. No mass can be felt. The abdomen is tympanitic in front as well as in the flanks. General condition is that of very marked prostration, the pulse being 120 and the temperature slightly above normal.

Immediate operation under gas and ether. A median incision four inches in length was made below the umbilicus, opening the peritoneal cavity, which contained a small amount of clear serous fluid. The small intestine was moderately distended and was caught beneath a firm band, extending from the omentum to what appeared to be an appendix epiploica on the wall of the cecum, but which may have been the region of the former appendix. The band was divided, the intestine released, and the cecal attachment of the band buried with a purse-string suture of catgut. The abdominal cavity was irrigated with a hot saline solution and was closed without drainage. Uneventful recovery. Primary union.

*Case VII.*—J. K., aged 22 years. Penetrating pistol shot wound of the abdomen. Laparotomy; recovery. Acute obstruction from a band and from kinking of the small intestine six months later; laparotomy; recovery.

Patient has always been robust. In June, 1902, patient received a pistol shot wound of the abdomen and was taken in an ambulance to Gouverneur Hospital, where, two hours after the accident, a laparotomy was performed, and eight wounds in the wall of the small intestine and two in the mesentery were closed with sutures. In order to minimize the risk of subsequent adhesion, each perforation, with the exception of two, which were in close proximity to the mesenteric border, were closed with purse-string suture of silk and one suture over this to secure firm apposition. The bleeding vessels in the mesentery were ligated with catgut. A very moderate amount of gauze drainage was introduced to the point of suture and the abdomen elsewhere closed. The patient made an uneventful recovery; the patient passed flatus twenty-four hours after the operation and on the second day the bowels moved to enema. At no time was there any nausea or vomiting. Primary union was secured except at the central part of wound through which the drain protruded, and this was closed entirely by granulation by the end of the fourth week. Since then the patient has enjoyed excellent health until five days before his admission into the Presbyterian Hospital. At that time, about six months after the primary operation, patient was seized with severe colicky abdominal pain and persistent vomiting. There was complete constipation, and the patient was admitted to the hospital in a condition of collapse, with a pulse of 120 and temperature of 102° F. On examination, the abdomen was greatly distended and everywhere rigid. The greatest pain and tenderness was just above and to the right of the umbilicus. The tympanitic note was general.

Operation on Dec. 24, 1902, under gas and ether. The peritoneal cavity was opened by a median incision just above and below the umbilicus. There was a considerable amount of clear serous fluid within it, and the intestine immediately presented in a greatly distended condition. In the lower part of the cavity other loops of intestine in an extremely collapsed condition were observed. A strong band extending from the omentum to the posterior parietal peritoneum with the small intestine beneath and tightly constricted by it was found in the posterior part of the abdominal cavity on the right side at about the level of the umbilicus. This was divided and the intestine released. In addition, loops of small intestine were found adherent to each other and to the mesentery and when these were divided and the intestine straightened out the adhesions were seen to have formed at the points where the previous intestinal and mesenteric perforations had been closed, the silk sutures being still plainly visible in the wall of the intestine. The separation of these adhesions left denuded areas so extensive that they could not be covered satisfactorily with any serous investment. They were accordingly covered with Cargyle membrane, and the intestines returned into the abdominal cavity after they had been thoroughly washed and the abdominal cavity carefully irrigated with hot saline solution. The abdomen was closed without drainage.

After the operation the patient was restless and at times delirious. He was given early and repeated rectal injections containing turpentine, and the sides and extremities of the bed were alter-

nately elevated and lowered. The bowels moved abundantly from the second day. The delirium ceased on the fifth day, and from then on the convalescence was uninterrupted. Primary union was secured. At the end of about three weeks patient left the hospital. About five weeks after the operation patient had some abdominal pain and vomiting, continuing for about twenty-four hours, which he ascribed to some indiscretion in diet. Since that time, however, the patient has been completely well.

## MEDICAL PROGRESS.

### SURGERY.

**Complications of Artificial Anus.**—In a paper dealing with this subject, H. Géraud (Rev. de Chir., August 10, 1903) takes up the pathogenesis, etiology, symptomatology and treatment of two of the most frequent complications, namely: Prolapse of the mucous membrane, and prolapse of the intestine itself. Eversion of the mucous membrane is usually present in artificial anus; but exaggeration of this condition may lead to more or less marked prolapse and constitute a real complication. In this event, a mucous cylinder is seen which may be from 3 to 11 cm. in length. This, at first thin, supple, and easily reduced, becomes thickened, ulcerated, and irreducible; in which case a radical operation is indicated. This latter consists in resection of the protruding mucous membrane; a sufficient margin being left to permit suturing the membrane to the cutaneous orifice. Prolapse of the intestine is simple or double, according as one or both ends protrude. It is usually preceded by eversion of the mucous membrane; the latter being forced out under the influence of intra-abdominal pressure and at a given moment, the intestine following it. The intestinal opening having no sphincter, there is nothing to oppose its escape. A large abdominal orifice is the most potent predisposing cause of prolapse of the intestine; the determining cause frequently being some muscular effort. Prophylactic treatment is most important. The patient should be advised to accomplish defecation in the horizontal position and without effort of the abdominal muscles. Violent exertion, overfatigue, and excess of nourishment should also be interdicted. The chief point, however, is the use of such an appliance as will allow the escape of gas while still exerting pressure, not only upon the borders, but upon the whole orifice. If the prolapsed intestine is reducible it may be replaced and sutured in position; or the mass may be excised like a tumor, the subsequent treatment being like that used by Mikulicz in prolapsus of the rectum. In the event of irreducible prolapse, ablation is imperative and the author favors Gosset's method.

**Toilet of the Peritoneum in Appendicitis.**—No one method is suitable for all cases, for they vary much in the extent of operative work required, and in the difficulties encountered. According to S. H. Weeks (Ann. of Gyn. and Ped., August, 1903), when the operation is made before pus has formed, or during the interval between the attacks, no pus being present, no drainage is necessary. The appendix being removed, and the region being dried with pads of sterile gauze, the external wound is completely closed. Where there is a circumscribed abscess, care should be taken not to infect the general peritoneal cavity by forcible irrigation, which is liable to force the purulent pus among healthy intestines. The wound and abscess cavity should be packed with sterile gauze. Where the wall of the abscess is firmly adherent to the anterior wall of the abdomen, and can be opened without opening the uninfected abdominal cavity, this should be done. The point of adhesion should be carefully searched for, and the abscess opened at this point. Careful search should be made for concretions, as the neglect to find and remove them may lead to a troublesome sinus. Here the abscess cavity should be carefully evacuated and cleansed with gauze pads, on irrigation, which can be safely used without fear of infecting the healthy peritoneum, after which the whole cavity should be packed with gauze. The greatest care should be taken not to break down the abscess wall at any point. A fourth and a very important class of cases includes those in which there is no protecting wall of adhesions, and the products of a septic peritonitis have flooded the whole abdominal cavity and the intestines are floating, so to speak, in the septic fluid. All these cases require the thorough removal of the septic fluid and a cleansing of the intestines, which sometimes may require their removal from the abdominal cavity. This cleansing is best done by means of irrigation, several times repeated. After thorough cleansing by irrigation and sponging, a glass drainage-tube, open at both ends, and a strip of gauze pushed through it from end to end, should be passed well down into the pelvic cavity, and the whole infected area packed with gauze. Strips of gauze should be packed in various directions among the intestines, so that perfect capillary drainage may be secured throughout.

**Detachable Plaster Cast.**—An ingenious method of applying a plaster cast, which will permit the carrying out the more modern treatment of fractures by combined immobilization and massage, is described by C. O. Bechtold (Jour. Am. Med. Ass'n., September 5, 1903). The cast is applicable to any part of an extremity where a cast or a splint can be used, but for convenience, he details that intended for a Pott's fracture. The novel element is the employment of a Gigli saw. The limb is covered with a stocking or wrapped up in cotton and a Gigli wire saw applied in the median line anteriorly and posteriorly. Both of these are secured by a few turns of plaster bandage and a third saw is applied along the sole of the foot and similarly secured. The cast is then completed by successive turns of the plaster bandage, but is made somewhat thicker than usually. Care must be taken to leave the ends of the saws free, and not to bend them at sharp angles. As soon as the cast is completed and before it dries, it is cut through by means of the saws, which may be readily accomplished in about ten seconds. A roller bandage is then applied to hold the two halves of the cast together. When they are fully dried, they may be removed as often as necessary for the application of massage, hot applications, and inspection.

**The Omentum as a Protective Organ.**—It is only within the last few years that the importance of this organ has come to be recognized. Its function has, however, never been thoroughly investigated, and the animal experiments of E. Renzi and G. Boeri (Berl. klin. Woch., August 24, 1903) should therefore prove of general interest. They investigated the function with especial reference to other abdominal organs, particularly the spleen. If the main stem of the splenic artery or vein in a dog is tied off, the spleen, after 2 1-2 months, still retains its integrity, and the circulation is almost undisturbed. It is probable that the omentum sustains the circulation, at least in part, for it is often found lying on the spleen, its vascularity is increased, and in separating the adhesions, considerable bleeding is caused. This activity of the omentum in restoring the inhibited circulation affords encouragement for such operations as

that of Talma's for a disturbed portal circulation. If the blood supply to the spleen is entirely cut off, the organ becomes necrotic. But even after several days the omentum is observed to have surrounded the organ and in ten days it has formed a dense network around the spleen, in the center of which lies the organ, encapsulated, diminished in volume, and in a state of disintegration. After twenty days, it is no larger than a nut, and enclosed in a fibrous capsule with walls about 2 to 3 mm. thick. In 2 1-2 months there is scarcely any trace of the spleen left, except a small fibrous nodule, almost complete absorption having evidently taken place. The animals gave no symptoms of this process going on in their interior. If the circulation is entirely cut off and the omentum excised as much as possible, encapsulation does not take place, the spleen becomes necrotic, but no absorption follows, and the animal dies within twenty-four to forty-eight hours. If this operation is done in two stages, the vessels being tied off about eight to ten days after the omentum has been extirpated, death does not come on until three to ten days later. Neither one of these operations alone is fatal, but death is caused when both are done together, and is due, the authors believe, to the extraordinary toxic qualities of the disintegration products of the splenic tissue. The absorption of these is more or less hindered by the encapsulation produced by the omentum. It was also determined that the same thing took place when a kidney was tied off; encapsulation by the omentum being followed by slow degeneration and subsequent absorption. Foreign bodies introduced into the peritoneal cavity were likewise surrounded by the omentum, and apparently remained without causing any further trouble. The authors believe that these observations not only clear up the question as to what becomes of certain internal organs which may become cut off from their circulatory supply, but also serves to indicate certain therapeutic applications which are rendered possible by what is now known of the functions of the omentum from these experiments.

**A New Method of Reducing Posterior Dislocations of the Hip.**—The following new method for sciatic dislocations of the hip is described by J. ELGART (Centralbl. f. Chirurg., August 22, 1903): The narcotized patient is placed on the floor, his dislocated limb held over the knee of the surgeon, with the patient's knee at right angles, and the pelvis steadied by an assistant. By seizing the leg at the ankle and pressing downward the head of the femur will move upward, the surgeon's knee acting as fulcrum. Inward rotation of the femur is also practised by pushing the leg outward. With the free hand, the prominent head of the femur is seized and pressed outward so as to assist its gliding over the cartilaginous ring.

**Acoine and Cocaine for Local Anesthesia.**—Good local anesthesia has been obtained by W. KRAUSS (Münch. med. Woch., August 25, 1903) by means of a solution containing acoine 0.025 gm. (½ grain), cocaine 0.05 gm. (1 grain), physiological salt solution 5 gms. (1¼ drams). The solution should be prepared fresh. The best results were obtained in (1) Enucleation of the eye. A syringeful is here injected along the muscular insertion of the recti muscles. (2) Strabismus operations of children and sensitive adults. Half a syringeful into the neighborhood of the muscle will suffice. (3) Small operations upon the conjunctiva. (4) All operations upon the lids. (5) Extirpations of the lacrymal gland or sac. (6) Occasionally for operations in the vicinity of the eye, as in the removal of dermoids.

**Treatment of Penetrating Abdominal Wounds.**—It is a mistake, according to H. GEBELE (Münch. med. Woch., August 18, 1903) to treat penetrating abdominal wounds in civil life, according to the same conservative principles as during war. In peace, the conditions of asepsis are better and the bullets have less force of penetration, and cause larger perforations of the gut, so that an early laparotomy is almost always indicated, especially since the symptoms of perforation or hemorrhage often make their appearance too late. Secondary abscess, perforation, and the formation of strictures, so common after expectant treatment, are also avoided. Intestinal wounds are best managed by intestinal resection and suture or Murphy button. Hepatic hemorrhage ceases after suture with heavy catgut. Injury of the spleen calls for splenectomy. Shock is no contra-indication for operation, but ether should be employed. Otherwise chloroform, preceded, if possible, by several doses of strophanthus, is the best anesthetic. Local anesthesia will hardly ever be applicable on account of the unavoidable traction on the parietal peritoneum. Postoperative shock requires subcutaneous salines. To avoid paresis of the intestines, the operation is performed as rapidly as possible, and a rectal tube is inserted soon after the wound is closed. If flatus is not expelled in twenty-four hours, 100 to 150 cc. of pure glycerin is injected through the tubes. In 3 to 4 times twenty-four hours the patient may receive small doses of castor oil. The injection of an aperient into the intestines during operation may also be tried. Atropine has had no effect in the writer's hands, but the paresis sometimes disappeared after two daily doses of one milligram of physostigmine salicylate.

**Spinal Cocainization with the Addition of Adrenalin.**—After the enthusiasm of several years ago had subsided, spinal anesthesia has gradually gone out of fashion, and it is doubtful if to-day it is still practised as routine in any clinic. The great danger of intoxication is responsible for this, but luckily experiments have not been wanting to reduce the risk and thus save an otherwise excellent method from complete oblivion. A. DÖNITZ (Münch. med. Woch., August 25, 1903) reports a number of experiments in cats, on the combined use of cocaine and adrenalin. Where both drugs were injected simultaneously, three times as much cocaine was necessary to kill the animals; if the adrenalin was injected six minutes before the cocaine, five times as much was required. The adrenalin itself in the usual dose is innocuous to both man and animals. The experiments were then repeated with surgical cases, and it was found that a much smaller dose of cocaine was necessary to bring about the desired anesthesia. The most severe operations could be done after half a centimeter of adrenalin solution (1:1000) diluted with the same amount of water and followed by 0.0075 to 0.015 cocaine. After effects were slight or absent entirely.

**Electrothermic Hemostasis.**—The following are the advantageous features that are claimed for this method when the Downes instruments are employed by A. GOLDSPOHN (Am. Jour. of Obst., August, 1903): (1) Patients are more comfortable after operation, because the nerves so treated in the stumps are insensitive, which is not true in the ligated stump; (2) as these pedicles are probably sterile, and become disintegrated and absorbed, they cannot give rise to adhesions of viscera, as we know that ligated stumps so often do. (3) There is less blood lost, because this procedure is complete and wholly an antecedent or preventive one, which is not so true of hemostasis by ligation, in which it is often better to avoid the formation of large stump by preceding ligation en masse, and to tie the individual spurting vessels after the severing incision has been made. And when this cut is made within the extent of the band of baked tissue, as can be done after the larger

forceps have been used, there is no show of blood on either side of the incision. (4) This method of hemostasis is certainly more nearly ideal, because it does not involve the introduction of a foreign body, and it is more nearly ideally aseptic than is the use of any kind of ligature material which always implies the possibility of its not being aseptic, either from defective preparation or from manipulation with the only omnipresent instruments (the hands), which cannot be boiled. (5) In vaginal hysterectomy it is superior (*a*) in cancer cases, because it most nearly destroys the tissues which otherwise compose the stumps or pedicles, and thereby diminishes the chance for a recurrence, both from imperfect removal of diseased tissues and from implantation or from manipulation with the only omnipresent in- every instance of this operation it is of distinct advantage, because it does away with a most difficult and tiresome form of ligation, and also the very objectionable use of clamps, etc.; (*c*) thereby facilitating a very important part of the operation, *e.g.*, closure of the intestinal cavity and an avoidance of a very important chain of intestinal disorders, which so often follow the sojourn of a foreign body within the peritoneal cavity; (*d*) by avoiding ligatures, it avoids danger of secondary hemorrhage, and also of infection from such ligatures, when they become infected before they are absorbed or cast off.

## PHYSIOLOGY.

**Heat Production and Metabolism of the Embryo.**—That the embryo of warm-blooded animals is subject to a very active metabolism, and that the developmental processes are accompanied by marked transformations of energy, are maintained by C. BOHR and K. A. HASSELBALCH (Skand. Archiv f. Physiol., July 23, 1903). They find that the value of the respiratory quotients, as well as a consideration of the chemical constituents of the egg and of the heat produced by oxidation of the egg, leads to the conclusion that the respiratory metabolism during the development of the embryo of the hen, is the result of the oxidation of the fatty constituents. The amount of energy estimated upon this basis, corresponds to the amount of heat that is produced during the entire period of embryonic life. As there is no ground for assuming that any other tissue than fat is a source of energy during embryonic existence, the authors believe that all the chemical energy produced in such large quantity leaves the egg solely as heat and is in no way concerned in the formation of new tissue.

**The Action of Glycerin and Veratrin on Striated Muscle.**—The interesting field of neuromuscular physiology is richly extended by the important discovery by C. G. SANTESSON (Skand. Archiv f. Physiol., Vol. 14, Nos. 1, 2 and 3) that in frogs injected with large doses (.5 to 1. gm.) of glycerin, if the nerves or muscles be afterward stimulated by means of very weak induced opening shocks, there occurs not a minimal single contraction but a tetanus of extreme height enduring for a long time. Curare does not prevent this action of glycerin on the muscles but reduces the excitability of the latter to a marked degree. If two muscle-nerve preparations from a frog poisoned with glycerin be examined, it is found that the one which is tested the later shows a greater excitability to induced shocks. The current of action produced in a pulsating frog's heart is sufficient to throw a muscle poisoned with glycerin into tetanus. Applied to a muscle directly, strong solutions of sodium chloride, sugar, veratrin and glycerin produce a more or less pronounced contracture, the last, however, increasing the muscular irritability besides. The veratrin-contracture with its slow rhythmical undulations remind one of the wave-phenomena inherent in sarcoplasm, as studied by Fano, Bottazzi and others. The following differences are noted between the contracture of veratrin and the tetanus of glycerin. The latter increases irritability more than veratrin. The form of the glycerin-curve is that of a tetanus; the form of the veratrin curve is one of a single contraction with contracture superadded. Continued stimulation increases the response in veratrinized muscle but diminished it in glycerinated muscle. There are marked differences in the form of action-current produced in these two forms, the latter displaying during the period of tetanus a continued vibration. The glycerin-tetanus spreads to neighboring muscles and seems to depend upon the fact that the muscle rendered abnormally irritable by the glycerin, is stimulated again and again for a long time by its own currents of action. While veratrin acts chiefly upon the sarcoplasm, glycerin affects all the structures of the muscle. Microscopical examination reveals in glycerinated muscle certain gaps in the periphery of many fibers. The significance of these is unknown. No coagulating effect of glycerin has been observed, its influence depending probably upon its power to extract water. The strength of this tetanizing power of glycerin depends, in the author's opinion upon the ease with which glycerin osmoses into the substance of the muscular fibers, increasing their irritability and conductivity. That an agent like glycerin, which, by virtue of its influence on the physicochemical properties of the muscle and only these, produces its effect, in the form of such uncommonly powerful changes in the functional capacities of this organ, is an argument in favor of the doctrine that the muscular contraction is brought about by a change in which physicochemical forces play the leading rôle.

**Contributions to the Phenomena of Narcosis.**—In studying the effect of narcosis by means of nitrogen gas upon the structures of the nervous system, F. W. FRÖLICH (Zeitschrift f. Allgemeine Physiol., Vol. 3, No. 1) found that nerves and nerve-cells are affected in the same way—in both narcosis diminishes the assimilation of oxygen. The oxygen that is stored up in the nerves is dependent on the partial pressure of this gas and can, in spite of deep narcosis, leave the nerve unhindered.

**Effect of Thyroid Feeding on Nitrogenous Metabolism.**—In treating a case of myxedema, J. A. ANDERSON (Skand. Archiv f. Physiol., Vol. 14, Nos. 1, 2 and 3) observed that thyroid medication brought about an increase in the metabolism of proteids, and that this increase cannot be prevented by excessive feeding of fats and carbohydrates. The author maintains that the thyroid gland elaborates a substance which stimulates the processes that make for the disintegration of the tissue-proteid.

**The Elective Conductivity and Osmotic Pressure of Animal Tissues.**—In an investigation of various tissues (heart and spleen of the turtle and muscle of the frog), G. GALEOTTI (Zeitschrift f. Biologie, Vol. 45, New Series, Vol. 27) finds that during the transition from life to death there is a reduction in electric conductivity, while the molecular concentration remains the same. From this it is concluded that during the process of death the reactions of the protoplasm are changed in such a way that the number of free ions is diminished, while the number of actively osmotic molecules is subject to little or no variation. It is possible to bring about similar reactions between proteids and certain salts artificially. They are of eminent significance from the standpoint of the physicochemical investigations of the proteid bodies. The onset of putrefac-

tion is accompanied by a marked increase in electric conductivity and molecular concentration, which can easily be explained if one take into consideration the fact that the splitting processes accompanying putrefaction cause a marked increase in the number of ions, and of electrically neutral but osmotically active molecules.

**The Source of Indican in the Animal Body.**—It has been established by experiment and clinical observation according to H. SCHOLZ (Hoppe-Scyler's Zeitschrift, June 19, 1903), that as the result of the activity of certain bacteria in the intestinal canal and in other regions (*e.g.*, in the pus of empyema), indol is formed, which, after absorption, is excreted in the urine as a salt of indoxyl sulphuric acid, namely, indican. It has been maintained by many authors that there are other sources besides bacterial putrefaction for indican. Its excretion in large amounts in fasting animals suggested the hypothesis that indol may be formed by the non-bacterial disintegration of albumin. Observations made by many authors in fasting animals and human beings have failed to find a constant verification of this phenomenon. Clinical observations have suggested many morbid conditions in which indol has been supposed to result from non-bacterial decomposition of albumin. Senator observed a much more marked indicanuria in chronic than in acute diseases, particularly in chronic wasting and inanition disorders. Other diseases in which an increased indican output has been observed, are gastric carcinoma, pleurisy, pneumonia, progressive phthisis, glycosuria and Addison's disease. The indicanuria accompanying alimentary glycosuria, as observed by Gilbert and Weil, was prevented by the administration of liver-extract. In none of the above diseases have all observers been able to confirm the statement that an increased secretion of indican results. Moreover, in no instance has there been excluded the possibility that the condition of the bowels and the form of diet (*e.g.*, meat diet in diabetes) might have been the cause of a bacterial indicanuria. Moreover it has not yet been proved that the microbic agents in certain infectious diseases in which indicanuria has been observed, are not able to cause the formation of indol. Again, authors have contented themselves with a mere qualitative determination of indican, which is, of course, unreliable. Some investigators, by means of injections of small non-toxic doses of oxalic acid and phloridzin, have been able to produce indicanuria. These observations the author has not been able to confirm. He reaches the conclusion that an increased indicanuria following causes other than putrefaction has not been proved.

**Blood Change After Hemorrhage.**—In comparing the effect of hemorrhage upon the composition of normal blood with that during the administration of iron and arsenic, E. P. BAUMANN (Jour. of Physiol., Vol. XXIX, No. 1), finds that hemorrhage produces a general deterioration of the blood and serum, especially of the former. The leucocytes are increased, the change consisting chiefly of an increase of the polymorphonuclear, occasionally of the mononuclear cells. The specific gravity of both blood and serum is less altered than the remaining factors. The solids, proteids, and total nitrogen of both blood and serum are more or less equally affected. The qualitative change in the serum-proteids consist in an increase of serum-albumin at the expense of the serum-globulin. The fibrin is increased and the coagulation rate shortened. The blood-ash remains practically unchanged. Hemorrhage during the administration of inorganic iron produces a general deterioration of the blood and serum, the latter being considerably less affected than by hemorrhage alone. The hemoglobin is increased above its original value, while the red corpuscles are even more diminished than by hemorrhage alone. The leucocytes, both quantitatively and qualitatively, are affected as by hemorrhage alone. The same applies to the specific gravity of both blood and serum, and to the solids, proteids and total nitrogen of the blood. The solids, proteids and nitrogen of the serum are affected in varying degrees. The alteration in the fibrin and the coagulation rate correspond to those produced by hemorrhage alone. Hemorrhage during the administration of organic iron produces alterations in the blood and serum closely resembling, but less pronounced than those under hemorrhage and inorganic iron. Hemorrhage during the administration of arsenic produces changes in the total blood which in every respect closely resemble those caused by hemorrhage alone, with the exception that the number of leucocytes is diminished instead of increased. The condition of the serum, however, resembles that produced by hemorrhage and inorganic iron, *i.e.*, it is better than under hemorrhage alone, but not so good as in hemorrhage and inorganic iron. Hemorrhage during the combined administration of iron and arsenic produces a degree of deterioration which is much less marked than that produced during the administration of either of these drugs singly.

**The Nature of Adrenalin Glycosuria.**—The subcutaneous administration of adrenalin in dogs and rabbits causes a true glycosuria and glycemia, according to D. N. PATON (Jour. of Physiol., Vol. XXIX, No. 3), the degree of which depends largely upon the amount of carbohydrates in the body, but which occur when stored carbohydrates have been eliminated. The glycosuria is apparently due to a diminished utilization of sugar in the tissues, since it is not due to a mere increased formation of glucose or to increased excretion of sugar by the kidneys. That the effect is due to a toxic action of the adrenalin and that it is not caused by an interference with the processes of oxidation due to the vascular changes, is indicated, first, by the extent of the glycosuria—which is far more marked than that observed as the result of mere interference with oxidation, and secondly, by the fact that the glycosuria is slight in guinea-pigs where the vascular changes are much more prominent. The observations of Herter support the view that the toxic action is not a direct one, but that it operates through the pancreas. During the prolonged daily administration of adrenalin, days may occur on which sugar does not appear in the urine. A distinct tolerance of the drug is established. Diacetic acid and aceton have not been detected in the urine of dogs, but a dark red ring at the junction of the urine with nitric acid is constantly present. The study of the proteid metabolism shows (1) That the sugar is not entirely derived from the breaking down of proteids, (2) that there is a markedly increased production of ammonia and (3) that, on an insufficient diet, the decomposition of proteids is markedly increased, while the absorption of proteids is not interfered with. The proteid metabolism under adrenalin thus benaves as it does in ordinary diabetes.

**Exercise and Urinary Secretion.**—The early excretion of sulphuric acid appears to be a constant feature in the metabolism which accompanies rapid muscular exercise, according to G. C. GARRATT (Jour. of Physiol., Vol. XXIX, No. 1). The acid seems to pass out in combination with potassium and ammonium, and the maximum output occurs several hours before that of total nitrogen. The increased excretion of phosphoric acid resulting from exercise bears close relation to that of free acid and urea. The acid appears to be eliminated chiefly in combination with the alkaline earths and am-

monium. The normal relation between sodium and chlorine does not seem to be conspicuously disturbed by exercise, nor is the usual influence of increase in the urinary water upon them prevented thereby.

**The Nature of the Pancreatic Ferments.**—Arguing from the results obtained in previous investigations and in the one on the precipitability of pancreatic ferments by alcohol, H. M. Vernon (Jour. of Physiol., Vol. XXIX, No. 3) concludes that the tryptic and rennetic ferments do not exist as independent chemical entities. On the contrary they form a single complex molecular group, of which various side-chains possess various powers, as of digesting proteids or of coagulating milk, which can be independently exerted. Moreover, these side-chains possess various degress of stability, and it is possible for them to be destroyed, one at a time, without the activity of the remaining side-chains being in any way affected.

**The Spleen and Hemolysis.**—The physiology of the spleen is still the subject of diligent investigation and heated debate. It has recently been shown that this organ has no important action as a blood forming organ. In studying the experimental evidence of the connection of the spleen with the breaking down of the blood cells, D. N. Paton and A. Goodall (Jour. of Physiol., June 15, 1903) find that the removal of the spleen is not followed by any rise in the number of erythrocytes or leucocytes. The excess of erythrocytes added to the blood by injecting the defibrinated blood of animals of the same species, disappears at the same rate in animals with and in animals without the spleen. Hemolytic agents my be divided into (*a*) solvents of hemoglobin from the erythrocytes and (*b*) toxic agents to the erythrocytes. Injection of the first class (water) leads to an exactly similar hemolysis and recovery in the normal and in the spleenless animal. The injection or administration by the mouth of the second class (phenylhydrazine and toluylendiamine) causes the following changes in normal and in spleenless animals: (1) A great destruction of both red and white cells results in an anemia which in many features closely resembles pernicious anemia, but which is completely recovered from about the twentieth day. (2) In the organs there is a very great deposit of pigment, which gives the reactions of free iron, occurs most markedly in the spleen (when present) and next most markedly, in order, in the lymph-glands, bone-marrow, kidney, liver and cortex of the suprarenal capsules. Most of the pigment is contained in cells—large leucocyte, or endothelial cells—or is deposited along the fibrils of connective tissue. The splenic reticulum may thus be mapped out by the pigment, active regenerative changes, leucoblastic and erythroblastic, are confined to the bone-marrow where megaloblasts are also found when the regenerative changes are most marked. These megaloblasts indicate a reversion to the fetal type of blood formation and are only found in the circulating blood of man in pernicious anemia and a few allied conditions. The only difference between splenectomized and normal animals is that about the fourth day a slightly less degree of anemia is produced in the spleenless animal, because of the less rapid and complete removal of the dead erythrocytes from the circulation. The anemia induced by feeding rabbits upon a diet poor in iron and proteid (rice), is more marked in spleenless than in normal animals, the spleen apparently acting as a storehouse for iron, which would otherwise be lost. There is thus no evidence that the spleen has any active hemolytic functions. It is rather a scavenger of the blood, removing dead erythrocytes, breaking down the hemoglobin and retaining the iron for use in the regeneration of the blood cells.

## PEDIATRICS.

**Antenatal Rigor Mortis.**—Rigor mortis is to be considered an unfailing sign of death and, according to the now almost generally accepted theory of Brücke, which has been proved by experiment, it results from a coagulation of muscular albumin. As the fetus is endowed with muscular structure the same as the child or adult, says C. E. Paddock (Am. Jour. of Obstet., August, 1903), it is subject to many of the diseases of later life. Certain of its muscles are subject to constant use for weeks before its birth and are subject to external stimuli. This being so, what reason have we for not believing that rigor mortis exists in the dead fetus? Proof that it does and that it has been recognized for many years has been shown in reported cases. The first reported case was that of of Chowne, Lancet, 1840. In the reported case the cause of death of the fetus may be summarized as follows: In 13 labor was complicated by hemorrhage, viz., in 4 placenta previa, in 8 accidental hemorrhage, in 1 varix. In 2 there was eclampsia and in 5 there was contraction of the pelvis and rigidity of the cervix, in 2 there were twins, and in 1 acute peritonitis, in 1 prolapse of the cord. Granting that rigor mortis occurs in the fetus the question might naturally be asked, How can the fact be explained that the condition is so seldom recognized? In answer to this the author says that often the fetus has gone through the rigid state before birth; again, owing to the feebleness of the muscles, rendered so by disease of the mother or fetus the rigor mortis is too feeble to attract the attention of the physician. Again, the fetus may be born before the rigor mortis commences. In this case the diagnosis of death has been made, and no further thought is given to it. Usually the death of the fetus occurs in the later stage of labor and delivery soon follows instrumentally or normally. Should the condition occur during the first stage or induced by operative procedure the condition is not usually noticed; the physician naturally gives his attention to the living patient, rather than to the dead child. The passage of the child through the birth canal may soften the fetal musculature and joints and so alter the condition, even though it be one of advanced rigor mortis, and it may not again resume rigidity. Cases are reported where the physician has practised artificial respiration on a child, blue and rigid, with the fetal heart beating, although the child was dead and in rigor mortis. The author has heard the fetal heart beat one hour and a quarter after birth, though there had never been any respiration. From a medicolegal standpoint it must be admitted that rigor mortis can occur before birth as well as after. The existence of a new-born dead infant in rigor mortis is not necessarily proof of life apart from a mother, that is of independent existence. It does prove, however, that the fetus was alive shortly before or during birth. Post-mortem changes can thus occur in the dead fetus as well as in the dead adult body and that the condition in each is regulated by the same laws. Furthermore, that the condition often complicates delivery by interference with its normal mechanism.

**Diseases due to Faulty Nutrition.**—The three most marked of these are rickets, scurvy and infantile atrophy, and W. N. Sullivan (Pediatrics, Aug., 1903) assumes that their chief etiologic factor is faulty feeding. Mothers think that the child will grow better if its food is strong, so they give whole milk at an early age, potatoes, meat and other such foods. It is claimed that rickets does not exist in Japan where the fats and oils of fishes and the blubber of whales enter plentifully into the diet. Young monkeys taken from the mothers and fed with vegetables and fruit and puppies fed on

meat develop rickets. Cheadle states that twenty litters of lions died successively of rickets, and the next brood grew up healthy on a diet of cod-liver oil, bones and milk. Milk, however good, unless properly modified, is not always a sound food for the child. Scurvy is most common from the ninth to fourteenth month and lack of fresh food is the most important cause. Proprietary foods and condensed milk produce more scurvy than all other methods of feeding. So-called acute rickets is in most cases rickets complicated with scurvy. Children with scurvy commonly present the following symptoms: anemia, intense pain on motion, spongy and bleeding gums, swelling of the legs. There may be purpura, ecchymoses, discharge of blood from the body cavities or pseudoparalysis. The disease may be confounded with rheumatism, stomatitis, rickets, sarcoma, osteitis and infantile paralysis. Fresh milk, beef juice and orance juice are the most effective remedies. In marasmus or infantile atrophy extreme wasting of all the muscular tissues takes place without, as far as we are able to make out, any disease of other organs. It may be dependent on grave intestinal disturbances of toxic or organic origin; the mucous and submucous tissues of the intestines show atrophic changes. The symptoms are: emaciation, lessened appetite, weak pulse, vomiting. In the ordinary cases a proper diet is soon followed by rapid improvement. Rotch found the most suitable milk one with low percentage of fat, high sugar and medium proteids, with increase of the fat as the infant gains in weight. A fair commencing formula would be fat 0.45, sugar 6.00 proteids 1.00, limewater 5.00.

**Endocarditis Following Diphtheria.**—It is not unusual for cardiac murmurs and an increase of heart dulness to appear in the course of diphtheria, the cause being weakened heart muscle, dilatation and relative insufficiency. In time the muscle recovers and the dilatation and insufficiency disappear. Hibbard detected a systolic murmur in 85 out of 1,052 cases of diphtheria, about 8 per cent. But endocarditis with a valvular lesion is certainly rare. In 220 post mortems of Councilman, Mallory and Pearce, seven cases of endocarditis were found, and in one a pure culture of the Klebs-Loeffler bacillus was obtained from mitral vegetations. Wright and also Howard have reported cases in which the bacillus was found in the endocardium. H. D. JUMP (Pediatrics, Aug., 1903) reports diphtheria in a girl of six years, accompanied by weak and irregular heart. On the seventeenth day she developed fever and a pulse of 120, with a soft systolic murmur at the apex and a sharp second pulmonic. The fever lasted three days and each day the murmur became harsher and louder. A year later at the apex there is a systolic thrill and a loud, harsh, high-pitched systolic murmur. Evidently this was a true endocarditis and not simple dilatation, and its relation to the attack of diphtheria leaves little doubt as to its cause.

## HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

**Biology of the Dysentery Bacillus.**—D. DOMBROWSKY (Arch. f. Hyg., Vol. 47, No. 3) finds that an amphoteric reaction is most suited for the growth of the dysentery bacillus. There is a remarkable power of adaptability, however, not seen with other pathogenic germs, such as the vibrio of cholera or the typhoid bacillus, and it is very well possible to get an abundant growth with a distinctly alkaline medium. When dried on cover-glasses, the dysentery bacillus will remain alive for from eleven to twenty-three days, depending on the temperature; there was no difference in this respect between cultures forty-eight or seventy-two hours old. In sterilized water, they retained their power of reproducing up to eleven weeks, on bread-crumbs five days and on bread-crust only two days, on potato three days. Skimmed milk proved to be a more suitable medium than ordinary milk. Probably the Shiga and Kruse bacillus are identical.

**Hereditary Cystin Diathesis.**—At the autopsy performed by Prof. Kaufmann of Basle on a 21½-months-old child that had died of gradual inanition, there were found, according to E. ABDERHALDEN (Hoppe-Seyler's Zeitschrift, June 19, 1903) on macroscopic examination of the internal organs, numerous white points which on microscopic investigation appeared as masses of partly round, partly angular plates, which were recognized as cystin crystals. This case was demonstrated by Kaufmann as the first in which an infiltration of the internal organs with cystin has been recognized. This substance was extracted from the tissues by means of ammonium sulphate from which it was isolated in the form of beautiful six-sided crystals. This was actually a case of deposition of cystin in the tissues. Of interest is the fact that in the same family two other children had already died under similar circumstances, one at the age of 9½ months the other at the age of seventeen months. Two male children survived who gave evidence, as examination of the urine testified, of the same metabolic anomaly as the first case cited. On investigation of the urine of the living antecedents of the children, the following results were obtained: Cystinuria was present in the father but not in the mother, and in the grandfather but not in the grandmother on the paternal side. The results of the autopsy on the case cited indicated that the cystin is very probably formed, not in the intestine, but in the tissues, as the result of a quite specific anomaly of the catabolism of proteid. This was confirmed by the following experiment: After all the free cystin had been removed from the spleen, the latter was boiled in fuming hydrochloric acid for six hours. Upon cooling the resulting solution was precipitated by means of caustic soda and allowed to stand for twelve hours. The residue after filtration was dissolved in 10 per cent. ammonium sulphate and precipitated with glacial acetic acid. The precipitate consisted of the characteristic six-sided crystals of cystin. Of greatest interest is the discovery of the progressive family transmission of this anomaly of metabolism. In the case cited the antecedents, both in the male and female side, were tuberculous.

**Destruction of Bacteria in Vaccine Pulp.**—The fact that minute quantities of potassium cyanide added to sea water prevented the growth of bacteria and permitted the delicate eggs of the sea urchin to develop, as shown by the experiments of Loeb, prompted H. R. GAYLORD and D. E. WHEELER (Am. Med., Aug. 29, 1903) to employ it for the purpose of destroying the bacteria in vaccine without injuring the essential organism, which is believed to be a protozoan. They allowed fresh vaccine to become contaminated with putrefactive organisms, and then treated it with varying strengths of potassium cyanide, from n/2000 to n/200. A number of children were vaccinated with this pulp. It was found that a solution of n/200 exerts a complete bactericidal action upon the vaccine without in any way affecting the specific organism. As the cyanide evaporates very rapidly, no toxic effects are possible, especially if the solution be placed in a vacuum pan at 36° C. These experiments also suggest that the organism of vaccine is of the nature of animal protoplasm, and is probably a protozoan.

**Pathology of Smallpox.**—Some interesting contributions to this subject have been made from a series

of five autopsies performed by W. R. STOKES (Bull. Johns Hopkins Hosp., Aug., 1903). Sections and cultures were also made from six non-fatal cases. He believes that the early skin lesions indicate that the primary infection takes place in the lungs, probably by inhalation. The poison when it enters the circulation, shows a selective influence on the epithelium of the skin and respiratory tract, and many cases are probably not further affected. The serious and fatal lesions are caused by the secondary infection from these, and the infectious agent is usually the *Streptococcus pyogenes*. This organism is so distributed through the lesions as to explain most of the visceral changes, such as thrombosis, local necrosis, and the various pulmonary changes. This streptococcus septicemia is the most striking feature of fatal smallpox, and if it were possible to overcome this condition by a special serum, the mortality from the disease would be greatly reduced.

**Accessory Pancreas.**—Seven cases of accessory pancreas were found among a large number of autopsies by C. THOREL (Virchow's Arch., Vol. 173, No. 2). The most usual site is the wall of the stomach and intestine and more rarely the mesentery. The oval, glandular body generally occupies the submucous layer, occasionally the muscular, and causes both an internal and external prominence. Histologically the structure resembles that of the main organ except that the cells are smaller, the lobulation less perfect, the ducts prominent at the expense of the parenchyma and the cells of Langerhans less abundant or absent altogether. Occasionally myomatous new-formation is observed. It is difficult to explain the presence of pancreatic tissue at such abnormal sites, but probably some of the embryonal cells destined to become pancreas were cut off from the rest and displaced by some unknown factor.

**Melakoplakia of the Bladder.**—This name has been applied to a very peculiar and hitherto undescribed condition of the bladder observed by v. HANSEMANN (Virchow's Arch., Vol. 173, No. 2). Studded over the mucous membrane there were a number of round or oval, yellowish prominences, in part ulcerated, in part surrounded by an inflammatory zone. Microscopically they consisted of aggregations of large cells, with peculiar inclusions, which gave the iron reaction. The cells did not seem to come from any of the elements of the surrounding tissues, nor were they looked upon as parasitic by a well-known authority, so that their origin and significance is not clear. The patients did not suffer from any urinary symptoms and had died of some other cause.

**Toxin and Antitoxin.**—The Ehrlich theory of immunity is becoming more and more popular, but an interesting article of M. GRUBER and C. F. v. PIRQUET (Münch. med. Woch., July 14 and 21, 1903) shows that it is really based upon faulty conclusions. There is no experimental proof that a multiplicity of poisons exists with each disease, of qualitatively similar action, but varying toxicity and affinity toward the antitoxin, such as Ehrlich assumed when he formulated his theory of a "poison spectrum." Likewise there is no reason to assume that toxins act differently than other organic poisons. The conversion of a toxin into a non-poisonous "toxoid" with undiminished affinity for the antitoxin is possible, but not strictly proven. Toxin and antitoxin have weak chemical affinities toward each other and in combining they follow the law of other chemical compounds of weak attraction. It is possible that occasionally molecular compounds of varying proportions are also formed. The long period of incubation and other phenomena are best explained on this hypothesis. The formation of antitoxin has nothing to do with toxicity and cell-immunity for (*a*) many innocuous substances can lead to the production of antitoxin; (*b*) animals not susceptible to certain toxins, will yet manufacture antitoxins; (*c*) despite the presence of a large amount of antitoxin, the susceptibility to a poison may still persist and even increase; (*d*) cell immunity can be acquired without antitoxin formation; (*e*) the antibodies are not formed in those organs where the toxin is most active. The specific antibodies are not normal constituents of the body; their production occurs only after the introduction of foreign matter and has the character of an internal secretion. It is due to unknown peculiarities in the molecular structure of this foreign matter. The non-poisonous toxin-antitoxin compound does not lead to the formation of more antitoxin, it is chemically of an entirely different structure than its two constituents.

## OBSTETRICS AND GYNECOLOGY.

**Chronic Inversion of the Uterus.**—The problem of successful reposition of an inverted uterus is almost entirely one of mechanics. According to REUBEN PETERSON (Am. Gyn., June, 1903), treatment must be directed toward increasing the diameter of the inversion ring, either by pressure exerted from within outward or through incision of the pillars of the ring. The following operation is advocated by the author as meeting the requirements of the condition: The inverted fundus is grasped with a volsella and pulled forcibly outward and downward. Another volsella catches the anterior vaginal mucosa in the median line just above the anterior lip of the cup and pulls it sharply upward. Through the vaginal mucosa thus rendered tense is made a transverse incision some 2½ inches in length. In order to avoid opening the bladder, this incision is made as close to the cervix as possible. The vesico-uterine pouch is opened, the cervix exposed and divided between two volsella. This incision is carried upward in the anterior median line of the uterus within one-third of an inch of the fundus. The inversion is now reduced easily, the fundus going upward and each half of the divided cervix being carried through half the arc of a circle and finally meeting so that the two halves form a complete cervix situated downward, not upward. A wedge-shape piece of the bulging uterine wall on either side of the incision is removed, as is suggested by Taylor. This is done to enable the retracted peritoneal edges to come together. The uterine incision is now closed by continuous catgut sutures. The needle was passed from the peritoneal surface down to, but not through, the uterine mucosa. A catgut suture is passed around each round ligament close to the uterus and each end passed through the anterior vaginal wall and tied after the fundus is returned into the pelvic cavity. This brings the line of incision in the anterior uterine wall up against the bladder peritoneum, at the same time giving support to the fundus, which has long been prolapsed. The various vaginal operations which have been advocated for the same condition the author divides into four groups: (1) Partial posterior colpohysterotomy (Küstners' operation), which gave four successes in six operations (Küstner), Perlis (Von Jordon) and two failures (Salin Weber); (2) complete posterior colpohysterotomy (Piccoli's operation); (3) partial anterior colpohysterotomy (Kehrer's); (4) complete anterior colpohysterotomy (Spinelli). The vaginal methods collectively show 26 cases, with only three failures and no deaths, or 88 per cent. successful.

**Tumors of the Round Ligament.**—These neoplasms are comparatively rare, or else operators have been very derelict in reporting them, says D. G. LEWIS (Am. Jour. of Obst., August, 1903). Here, as elsewhere, little is known of the etiology of these growths. Menstrua-

tion provokes a temporary increase in the volume of the neoplasm. We have nothing to make us agree with Sänger that the traction of the displaced uterus may play a causative rôle. To trauma we are not justified in ascribing a causative action. Some of the tumors are situated directly over the external orifice of the external inguinal canal, others at the upper extremity of the labium majus, while some are found where one finds no trace of normal round ligament tissue, *e.g.*, about and below the labium majus. In rare cases the tumors are elongated, cylindrical, taking the form of the little finger. Usually they are single, though they may be multiple. The macroscopical appearance varies according to the histologic nature of the growth. The fibromyoma of the round ligament are like those of the uterus, susceptible of undergoing varied degenerations, benign and malignant. The lipomata present themselves under two forms: (1) When the tumor is developed in the continuity of the round ligament with normal elements of the ligament running through it; (2) when the growth is developed at the expense of the fatty mass of the labium majus. The tumor, usually painless, becomes at the monthly periods the seat of a very sharp pain, which radiates into the corresponding lower extremity, the lumbar region and the pelvis. At this time palpation become painful, and the neoplasm also shows a transitory increase in its volume. In the interval between the periods the tumor is generally painless; sometimes, however, without appreciable cause, little by little, it becomes distinctly painful. To the permanent or periodic suffering we must add the distress, more or less considerable, from walking, in cases where the tumor occupies the labium majus. A tumor of the extra-abdominal portion of the round ligament is differentiated from: (1) an ordinary reducible inguinal hernia of bowel or omentum, or both by the absence of reducibility, impulse on cough and tympany on percussion; (2) from an incarcerated adherent, or irreducible hernia, by absence of impulse on coughing, history of reduction on previous occasions, *e.g.*, before reduction had become impossible, absence of any history of nausea or vomiting; (3) from strangulated hernia, by absence of the above signs, and the grave symptoms incident to all bowel strangulation, shock, increased pulse rate, nausea and vomiting. The prognosis depends upon the histologic structure of the neoplasm. The only treatment applicable to these tumors is extirpation, and this should be done early or as soon as the tumor is recognized. Some operators, after having ligated the round ligament, have simply abandoned it in its place; others have fixed the ligament to the wall of the canal.

**The Present Position of Hysterectomy for Fibroids.**—What has a woman to gain in this operation? says Skewekeith (Am. Gyn., June, 1903). In some cases, nothing at all; in very many, very little indeed. In some a life of comfort and happiness, as against a life of misery; in a few, life inself. In an advanced case of ovarian disease, be the local difficulties what they may, one can honestly encourage a woman to run any amount of risk. She has not much to lose—a few months only, it may be, of everlasting suffering—and she may gain much by an operation, having much to gain. It is quite different in the case of nineteen-twentieths of those who have a simple fibroid tumor. The lists of operations are very unsatisfactory, as there is no standard to go by, and descriptions are so often recklessly indiscrete, incorrect and careless; for example, we find a tumor described as "large," or "the largest I have ever seen." The real reduction in the death-rate has taken place and has been brought about by discarding the clamps, the extraperitoneal operation, and the adoption of the intraperitoneal treatment of the neck of the uterus or complete hysterectomy. It is difficulty, nay impossible, to lay down any positive rule for the performance of hysterectomy, for it is very seldom that it is absolutely necessary to resort to this operation to save life; whereas one must always advise the removal of an ovarian tumor. In the following cases, however, one may say that hysterectomy ought to be the rule: In all fibrocysts, in all edematous tumors when accompanied by profuse watery discharge, in all large tumors causing symptoms, and when a patient is under fifty years of age. Even when a patient is over thirty years it may be worth while to remove a tumor weighing 30 or 40 pounds. In small tumors extending as high as the umbilicus or so, fibrocysts and edematous tumors excepted, the writer, as a rule, advises Apostoli's treatment. This form of treatment does not seem to have been very successful with some. Nor is this to be wondered at if the accounts received from patients treated by others are in any way correct, for it has seemed to resemble Dr. Apostoli's treatment simply in that a battery was used.

**Vaginal Incision in Sepsis Following Abortion.**—The following alarming statements are made by Hunter Robb (Am. Gyn., June, 1903), to the effect that (1) of all married women who die between the ages of twenty and thirty nearly 10 per cent. succumb to a puerperal infection; (2) at the present day, in private practice, at least, the mortality from childbed fever is nearly as high as it was forty years ago. Such a confession is astounding and humiliating, and we must of necessity come to the conclusion that the advantages of aseptic and antiseptic procedures are either chimerical or that the belief in them is still to a large extent more theoretical than practical. So far as the author's own experience goes, the remote results of a septic process following labor or an abortion, implicate more particularly the fallopian tubes and ovaries in 40 to 60 per cent. of the cases. As a rule the infection begins in or near the external genitals. And, provided it is of a virulent nature, it implicates successively the structures of the vagina, the cervix, the uterus and the fallopian tubes, and thus extends to the peritoneal cavity. At other times it reaches the peritoneum through the uterine walls by way of the lymphatics or blood-vessels. Accompanying the inflammation there is often an exudate, which may accumulate in the peritoneal cavity or may remain sealed up in the fallopian tubes. The exudate may be of any form or mixture of forms. If absorption of the exudate does not occur, organization takes place, with the formation of adhesions, which bind down the tubes and ovaries more or less firmly, and thus interfere with their functions. In this way various symptoms are produced which cause the patient a greater or less amount of inconvenience until the adhesions are separated. Under such circumstances we have two problems to solve: (1) How can we insure to the patient the best chance for her life? and (2) How can we, at the same time, prevent the occurrence of unfortunate sequelæ? The author advises the following method of dealing with an infection after an abortion: The cavity of the uterus is first cleaned out to prevent the continued absorption of toxins from any infectious material which may be present, and thus, at least, limit the intensity of the process. For this the finger alone is employed, or combined with the curette. The cavity of the uterus is washed out with hot saline and two ounces of peroxide of hydrogen; it is then cleansed with saline solution and sponged dry. After this two or three drams of iodoform powder are placed into the uterine cavity, which is then packed with sterile gauze. Now the cul-de-sac is freely opened, and after evacuating any fluid

which may be present, it is irrigated with hot saline, followed by two ounces of peroxide of hydrogen. This in turn is washed out and the cavity wiped dry. Lastly, two or three drams of sterilized iodoform powder are dusted into the cul-de-sac, after which it is packed tightly with strips of sterile gauze. By this procedure the author believes that two advantages are obtained: (1) By evacuating the fluid from the cul-de-sac further absorption is prevented; (2) the ovaries and fallopian tubes are saved by preventing adhesions which would almost invariably form as a result of the organization of the exudate. The author's experience has shown that the secretions from the uterine cavity are almost always sterile, while organisms are invariably found in the exudate in the cul-de-sac.

**Peritoneal Adhesions.**—The relation between peritoneal adhesions and the functionating uterus is the subject of a most interesting paper by Chas. B. Reed (Am. Jour. of Obstet., August, 1903). Inasmuch as 80 per cent. (Winckel) of the female bodies which come to the post-mortem table show the effects of peritoneal inflammation in some form, it seems remarkable that cases of function disturbances of the uterus are not more frequently reported. Many factors combine to place the uterus and its vicinity first in point of susceptibility to inflammatory adhesions. Its varied functional activity, its rapid change of form, size, position and consistency—its proximity to organs containing infectious material and the open communication which is afforded by the tubes with the pelvic cavity, and vagina with its manifold possibilities for infection, all unite to produce a predilection for adhesions, which some authors claim as high as 75 per cent. It is a relatively common occurrence to find adhesions between the rectum and uterus and ovaries, which locally produce changes in the peristalsis and nutrition of the rectum, such as catarrh, diarrhea, stricture, coprostasis, and even paralysis, ileus and death. In addition to the general symptoms, there is also to be found locally that all the activities of the uterus are more or less impaired by interfering conditions. It is very noticeable, however, that the functional disturbance is in no way proportionate to the extent of the peritonitic changes, but rather to the anatomical location of the adhesions. The menstrual function may be primarily, seriously involved. Thus a persistent and violent dysmenorrhea is to be found in many cases, where the uterus is bound to the intestine, appendix, omentum or abdominal wall. To substantiate the effect of adhesions as an agent in the cause of sterility, we must appeal largely to theoretical considerations. One etiological factor would certainly be the existence of dyspareunia in the presence of adhesions and inflammatory residues. Adhesions may play an important rôle in the determination of a tubal pregnancy by the construction of the lumen, as in the historical case of the wandering of the ovum, reported by Weber von Ebenhoff, where the right tube was obliterated; the corpus luteum was found in the left ovary and the fertilized ovum in the end of the right tube. The presence of adhesions undoubtedly produces many abortions and influences a certain percentage of fetal and placental anomalies. It is well recognized that sterility and tubal pregnancy may result from such conditions, and it is also probable that pregnancy and labor are rendered pathological by the presence of adhesions far oftener than the literature would indicate. Many adhesions are undoubtedly destroyed by the growth of the uterus in pregnancy, but the rupture of the same may be attended with fatal hemorrhage. Adhesions between the uterus and movable organs of the abdomen are only rarely a source of danger or a cause of death.

## THERAPEUTICS.

**Alcohol Compresses.**—This method of treating local inflammatory processes, first advocated by Salzwedel, has been modified by Beschorren (Deut. med. Woch., 1903, No. 28), in order to avoid the smarting caused by the application. To the alcohol he adds an equal amount of a one-per-cent. solution of aluminum acetate, which raises the temperature of the fluid several degrees and makes it more soothing. The moistened gauze is applied directly over the inflamed area and a piece of rubber tissue, with more gauze over this. A perforated impermeable bandage is then wound around the parts.

**Adrenalin in Typhoid Hemorrhage.**—A severe case of typhoid hemorrhage, occurring in the practice of B. Graeser (Münch. med. Woch., July 28, 1903) was virtually saved by the prompt use of adrenalin. Thirty drops of the commercial solution were given every three hours in physiological salt solution. No ill effects were observed. Although it is improper to judge from one case, the patient had been bleeding steadily with all the other drugs.

**Toxic Symptoms Following the Use of Aspirin.**—Some very strange toxic symptoms were noticed by Franke (Münch. med. Woch., July 28, 1903) after the ingestion of one gram of aspirin. In fifteeen minutes the upper lip began to swell and deglutition became painful, while pulse and respiration was very much increased. The swelling soon extended over the entire head and was not relieved by cold applications. Somewhat later an extremely troublesome urticaria made its appearance over the entire body. The following day all the symptoms had disappeared, and with them the attack of influenza, for which the aspirin had been given. Probably the condition was one of phenol poisoning from splitting up of the drug in the stomach, since the urine contained large amounts of phenol.

**Albuminuria in Aortic Insufficiency.**—Albuminuria is a common condition in chronic endocarditis as soon as there is a disturbance of compensation, which brings with it venous stasis. At first this will disappear with digitalis, but later, when anatomical changes have taken place in the kidneys, no drug will be of much avail. This change of simple congestion to cyanotic induration manifests itself clinically in increased excretion of urine containing albumin, fatty renal epithelium and granular cylinders, while the other symptoms of stasis are relieved or disappear with treatment. V. Leube (Münch. med. Woch., July 28, 1903) classifies the possible causes of an albuminuria as follows: (1) A complicating parenchymatous nephritis may exist, as where the endocarditis is caused by diphtheria. The nephritis is generally amenable to treatment, while endocarditis persists. (2) There may be a general atheroma which also involves the renal vessels, leading to arteriosclerotic kidney. This is especially common with aortic insufficiency. (3) When the energy of the heart sinks and the cardiac muscle undergoes fatty degeneration, stasis, followed by cyanotic induration, is found in all the organs. This occurs only in the later stages of aortic insufficiency. Besides this there is, however, another form of albuminuria, characteristic for the early stages of aortic insufficiency and not accompanied by cyanosis, edema, etc. The urine is not diminished in amount, the specific gravity is relatively low, and the amount of albumin, hyaline and granular casts very slight. Pathological examination of a few kidneys of this kind show that the marked variations in pressure are responsible for certain anatomical changes. The walls of the arteries and capillaries are found much thickened, so that the amount of blood carried to the kidneys must necessarily be less than normal. The liver and spleen show similar lesions, but never the lungs.

## GALL-STONES.

We have had occasion to comment on the truly memorable meeting of the Association of American Physicians, held in Washington last spring, noting particularly the illuminating discussion on diseases of the gall passages and their treatment. One of the most notable papers read at that discussion was that of Dr. C. A. Herter, on the Etiology and Chemical Pathology of Gall-Stones, which is concluded in this week's issue of the Medical News.

While Dr. Herter makes it very evident that there are a large number of unsettled points essential to the full understanding of the many intricate questions relative to this problem, he at the same time gives us an illuminating résumé of the solid grounds for reasonable deductions, and a noteworthy series of suggestions as to the most fertile fields for future investigations.

That all gall-stones are not alike is very manifest, and that pathology in future must differentiate between the modes of formation of cholesterin stones and bilirubincalcium concretions is imperative. Moreover, a careful study of this paper will tend to show that the problems are not as easy of solution as our text-books have led us to believe.

Stagnation of the bile—bilious diathesis, torpid liver, and similar delusive terms receive somewhat of a setback as we read that mere concentration of the cystic contents has probably little to do with the production of gall-stones, of either variety, and that retardation of the flow of the biliary secretion probably must be associated with other factors, notably cystic infection, in order that the train of circumstances leading up to calculous formation may become operative.

The antiseptic qualities of the bile, so dearly loved by those of a teleological cast of mind, are probably non-existent, and interference with the free flow of the liver secretion seems to offer just the opportunity for the ubiquitous bacterium.

Dr. Herter tells us further that there is a tendency, perhaps, to exclude from the mind other than the bacteriological features concerned in the formation of gall-stones, now that in recent years so much important verifiable research has been conducted along the line of cystic infection. While it may be true that infections from a number of organisms may play very large, maybe the most important rôles, metabolic factors should not be lost sight of. His suggestions relative to the problems of excessive fat diet we believe are of far-reaching importance and promise much for the investigator.

Summing up, he says: "It is plain from what has been said that there is at present no unequivocal evidence that gall-stones arise from constitutional derangements unconnected with microorganic invasions of the gall-bladder. On the other hand it is certain that the cholesterin of the bile can be considerably increased by local irritants unconnected with infection and it is likely that the requisite local conditions for such increase sometimes arise through purely metabolic disorders. While gall-stones are commonly the result of local infections we should carefully guard against the conclusion that they can never have a diathetic origin. It is at least highly probable that diathetic conditions are capable of so altering the composition of the bile as to materially favor the production of calculi in the presence of suitable local bacterial activities."

We trust that Dr. Herter may be permitted to continue his studies along this line, feeling that his work on therapeutics will open up a new vista in the purely medical treatment of gall-stones.

## THE WIDENING ROLE OF INFECTION.

There are not a few medical men who have been thoroughly persuaded for some time that the applications of bacteriology to medicine were

at an end and that far from further specific microbic disease agents being discovered there would be a reaction that would make bacteriology of much less importance in the science of medicine than has been hitherto supposed. As a matter of fact, however, each succeeding year brings new diseases within the scope of bacteriology and is making it ever clearer that the study of minute life holds the mysteries of disease that have thus far proved so hopelessly puzzling. There are very few general practitioners now who are not distinctly of the opinion that rheumatism is an infectious disease due to a microbic cause even though up to the present time none of the micro-organisms found in tissues affected by the disease have been proven to be the specific cause of rheumatism.

After all, since the demonstration that pneumonia is due to a specific bacterial agent, it is not a matter for surprise to find that other affections, supposedly dependent on variations in temperature, or on dampness and exposure to cold, are really due to the fact that specific microbes find favorable opportunities under such conditions of exposure to obtain that hold upon the tissues which enables them to produce their serious effects. It seems very clear now that the various forms of colds that is, the various catarrhal conditions which so frequently follow exposure to unexpected changes of temperature, will eventually prove to be due to a number of differing forms of bacteria. Each successive winter with its stock of clinical and bacteriological observations apparently brings us nearer to the acceptance of this conclusion.

In another and quite different line, the rôle of infection is becoming equally important. Many skin lesions have proved to be due to bacteria of various kinds, although in the beginning of bacteriological work in dermatology there seemed to be very little hope that specific causes for cutaneous diseases would be found. The fact that individual reaction is so important in cutaneous disease seemed to point to the conclusion that not specific causes but altering natural conditions were the etiological agents. At the present time, however, the importance of bacteriology in this department of medicine is very generally recognized. In the familiar disease baldness, Sabouraud's observations seem to show the almost constant presence of a specific microbe in all cases of ordinary premature baldness. Even the remote conclusions that flow as corollaries from Sabouraud's teaching present little difficulty to many minds. Not only the infectiousness of baldness, but its possible contagiousness is urged by many.

With these extensions of the doctrine of the bacterial origin of still further diseases in mind, it is not surprising to find that in the nervous system, too, the rôle of the bacteria is coming to be recognized as an important etiological element in the production of disease. Such a condition as myelitis is frankly conceded as secondary in most cases to some infective process in other organs. Even an ordinary furuncle may under unfortunate circumstances prove a source of infectious material that by its ravages in the central nervous system may prove fatal or leave the patient a hopeless paralytic. Supposedly functional nervous diseases are yielding to the same etiological explanation and so it is not a matter for surprise to find that in the discussion of chorea at the recent meeting of the British Medical Association many good authorities did not hesitate to express the opinion that it is an infectious disease, very probably due to a specific bacterium. There are even investigators who consider that they have isolated the bacterium in question. As there is a manifest relationship between rheumatism and chorea this conclusion in the light of recent alterations of opinion with regard to rheumatism might almost have been expected. It is evident that there is still a rich field open for bacteriological investigators and discoveries of importance lie only just behind the veil.

## ECHOES AND NEWS.

### NEW YORK.

**Hospital Cornerstone Laid.**—The cornerstone of the new building for St. Mary's Hospital in Jamaica was laid last week by the Very Rev. Mgr. McNamara, Vicar General of the Diocese of Brooklyn. The hospital building when completed will accommodate about 300 patients. The institution, which now has rather cramped quarters, is conducted by the Little Sisters of the Order of St. Dominic.

**Trachoma Campaign.**—Dr. Lederle has caused a circular letter to be mailed to the board of directors of every hospital and dispensary in the city, asking the cooperation of each institution in the efforts to stamp out trachoma in the public schools. Dr. Lederle proposes to apportion the school children needing treatment in the various districts among the several dispensaries, the pupils being claimed as patients of the dispensaries nearest their homes. He asks that careful record be kept of each child's attendance for treatment, in order that the Health Board inspectors may keep the children under close surveillance. Dr. Lederle's three most important requests are: To permit this Department to print the name and address of your institution on the back of cards given to children excluded from school, in order that those living in your neighborhood may attend your institution for treatment. To

request the surgeon in charge of your eye department to stamp the date of each visit made by a school child on the back of the card given to the child by the inspector for this purpose, in order that the inspectors may be assured that treatment is being regularly attended to. Date stamps will be furnished by this Department on application. To refer cases requiring operation, if you so desire, to the hospital organized for this purpose by the Department of Health. Upon a chart in the office of the President of the Health Board is marked with colored pins the location of all the dispensaries and public schools. Close watch will be kept upon reports for results of the new scheme, and, if this fails, other and more vigorous means for treating school children for the eye disease will be put into operation.

**The Health Board and the New Regime.**—The conditions which existed under Col. Mike Murphy and John B. Sexton, the Tammany Commissioners of Health, are compared with the new order of things under Ernst J. Lederle, the present Commissioner, in a pamphlet issued last week by the Citizens Union. Smallpox reached the high-water mark in the autumn of 1901, under Tammany, but as a result of 810,280 vaccinations in 1902, only 44 cases have been reported this year and but 3 deaths. A decrease in the number of deaths from consumption is also credited to Fusion. The document says: Out of 70,720 deaths in Greater New York in 1901, 8,135 were due to consumption. No strong measures were being taken to stamp out the disease. In 1900 the deaths had numbered 8,154. Under Dr. Lederle in 1902 the deaths were reduced to 7,569, a death rate of only 2.03, against 2.30 in 1901 and 2.37 in 1900. The Department is now planning, in cooperation with the Board of Trustees of Bellevue and allied hospitals, a municipal sanitarium outside the city, to cost $500,000 and to be under the charge of the trustees of Bellevue and allied hospitals. Although the plan has not yet come formally before him, it is understood that the Mayor will sanction it. A dispensary for tuberculosis treatment is now building next door to Department headquarters. The article says that people who came off North Brother Island during Tammany control declared that it was worse than the Black Hole of Calcutta. It adds: It has been evident for years that North Brother Island has been a name to be dreaded by the poor of this city. The rich who were attacked by contagious disease could be properly isolated and treated at their homes, but the poor people were carted off to North Brother Island and there, according to popular tradition, ill treated, half starved, and neglected. This tradition had the result of teaching the poor to conceal the presence of contagious disease among them rather than run the risk of having members of their families taken away to the island. Since January 1, 1902, the Department has spared no effort to eradicate this belief. This has been done, first, by putting the medical corps and superintendence of Riverside Hospital into competent hands, so that patients should have the best of medical attention, food, and general treatment. To add to the comfort of patients, a telephone system was installed in all the pavilions, so that friends of patients might have communication with them at all times in case of necessity, or when it was felt that messages from home might help the progress of the patient toward recovery. Visiting days were also established for the friends of patients, and the means of communication with the island were improved, so that there should be no reason why, within the limits of safety from contagion, North Brother Island should not be as freely visited as any other city institution. All this appears to have had a good effect, for patients have gone back to their friends and told them that the commonly expressed fears regarding the treatment there prove now to be baseless. The concealment of contagious cases has now almost entirely ceased. A death rate of 18.75 in 1902 was a saving of 4,500 lives, the report says. For 1903 the death rate is likely to be 18.

**Memorial Hospital Sold.**—The Memorial Hospital for Women and Children, Classon and St. Mark's avenues, Brooklyn, was sold under foreclosure proceedings in the Brooklyn Real Estate Exchange last Tuesday. The Dime Savings Bank had a mortgage of $50,000 on the property under date of June 7, 1895. The hospital authorities were unable to pay the interest, which was in arrears for several years. There are several other claims against the corporation. Clifford S. Kelsey, who, it is understood, acts for the Jewish Hospital Society, of which Abraham Abraham, of Abraham & Straus, is president, bid it in for $96,500. Mrs. Jennie V. H. Baker, chief of the medical staff of the Memorial Hospital, said that the property had been purchased by the Jewish Hospital Society.

## PHILADELPHIA.

**Under Water Five Minutes.**—To settle a dispute, George Kistler, swimming instructor at the University of Pennsylvania, recently remained under water five minutes and five seconds. It is stated that an examination by a physician following the feat showed no departure from the normal except some acceleration of the heart's action.

**State Homeopathic Medical Society.**—The Thirty-ninth annual meeting of the Homeopathic Medical Society of the State of Pennsylvania was held at Scranton September 22, 23 and 24. The program included a wide range of topics which were discussed by the leading homeopathists of the State. The meeting was held under the presidency of Dr. O. S. Haines, of Philadelphia.

**Columbia's New Hospital.**—The new hospital at Columbia, Pennsylvania, built and equipped at the cost of $40,000, has recently been formally occupied. The building is of Columbia brick ornamented with Indiana limestone. It is three stories high with a frontage of 88 feet. It consists of a main central portion with a wing on either side and an annex in the rear of the central building. The citizens of Marietta contributed $1,000 toward the erection of the building, in recognition of which a portion of each public ward has been named the "Marietta Section."

**Jewish Hospital Improvements.**—Three new buildings, which have recently been added to the Jewish Hospital, are to be dedicated on October 4. They are the Guggenheim Hospital for private patients, the Eisner home for nurses, and the Loeb operating building. The first of these will accommodate 40 patients. The nurses home is a three-story building with accommodations for 35 to 40 nurses. The Loeb building contains an operating room 16 by 24 by 15 feet in size.

**Vaccine Physicians will Examine Pupils' Arms.**—The Board of Education has granted authority to the vaccine physicians of the city to visit the public schools and examine the arms of the pupils to determine if they possess good vaccination marks. Under the instructions issued, the vaccine physicians are not permitted to vaccinate any of the

children in the schools. When it is found that revaccination is necessary, the pupils are directed to so inform their parents, and will not be permitted to return until the operation has been performed, and been successful.

**Typhoid Fever Traced to Milk Supply.**—Infected milk and defective sanitary conditions and not an impure water supply are shown by Chief Abbott, of the Bureau of Health, to be the cause of the numerous cases of typhoid fever reported during the past few weeks from the Twenty-first Ward, where only filtered water is furnished. Dr. Abbott in his report says that the conclusion reached is, in brief, that the unusual number of cases of typhoid fever in the Twenty-first Ward is not due to the water supply, else there should be a corresponding increase in the Twenty-second Ward, receiving essentially the same supply. This is not the case. All the accumulated evidence points to the accidental infection of two milk supplies as the probable cause of the sudden outbreak and, finally, that unless certain defective sanitary conditions now existing in the ward be corrected, we may look for a repetition of this accident in spite of the fact that the population of those two wards is receiving a water supply of the very best grade. The official records of the bacteriological analysis of these waters made at brief intervals during the last six weeks or more point to nothing that would suggest the water in any way at fault. The investigation of the milk supply showed that of the 78 cases of typhoid fever in the Twenty-first Ward occurring since August 1, 41, or approximately 53 per cent., were found to have purchased their milk from a single dealer. Two cases of typhoid fever are known to have developed in this household. As milk is one of the best vehicles for the conveyance of typhoid fever infection, it seems fair to suspect that the disease in the ward in question is due to the use of milk that was in one case accidentally infected by the dealer in whose family the disease existed. As to the general sanitary condition of the neighborhood, Dr. Abbott says, that a "careful survey of the neighborhood reveals the fact that many of the properties have no connection with the street sewers, their facilities for drainage and disposal of waste being over the surface and into the cesspools located in the back yards. There is conspicuous lack of sewage facilities in the Twenty-first Ward. A number of streets have no sewers under them and a very large number of houses located in many instances on streets having sewers are not connected. With the continuation of a condition of this kind, it is obvious that we must anticipate from time to time such epidemics as the one now engaging our attention.

**Phipps Institute.**—The Henry Phipps Institute for the Study, Treatment and Prevention of Tuberculosis has arranged for the coming fall and winter a series of lectures by well-known physicians on the various phases of tuberculosis. Some of these lectures will be more or less popular in character and all will be free to the public. The Auditorium of the Witherspoon Hall at Juniper and Walnut streets, Philadelphia, has been selected for the purpose, having a seating capacity for nearly 1,200 people. The first of these lectures will be given by Dr. E. L. Trudeau, of Saranac Lake, N. Y., during the last week in October, his subject being "The History of the Development of the Tuberculosis Work at Saranac Lake." The following gentlemen have been invited to give the subsequent lectures: Dr. Pannwitz, of Germany, in November; Dr. William Osler, of Baltimore, in December; Dr. Calmette, Director of the Pasteur Institute, at Lille, France, in January; Dr. Herman M. Biggs, of New York, in February, and Dr. Maragliano, of Italy, in March. All of them have accepted with the exception of Dr. Calmette, who will come, if it is possible for him to leave his work in connection with his Institute, and the International Congress on Tuberculosis, to be held in Paris in 1904. Subjects and exact dates will be announced as soon as possible. The Director and members of the staff of the Henry Phipps Institute extend a most cordial invitation to the profession in general to attend these lectures. It is greatly desired that this inaugural series of lectures will prove a success and be largely attended.

The following additions to the staff of the Henry Phipps Institute have been made: Dr. M. P. Ravenel has been appointed Assistant Medical Director and Chief of the Laboratory; Dr. E. A. Shumway has been appointed Ophthalmologist, and Dr. J. F. Wallis has been appointed Dermatologist.

## CHICAGO.

**Superintendent of Compulsory Education Censured by Health Department.**—The Health Department characterized the recent attempt of the Superintendent of Compulsory Education to operate a special health department, as "meddlesome, mischievous and sensational." Among other things, the Bulletin says: "Physicians of Chicago, school principals and teachers and parents of school children are officially notified that they are not required, either by State law or city ordinance, to report cases of contagious disease, suspected or actual, to any authority except the contagious disease division of the city health department. This public notice was made necessary by a renewal of the efforts of the Superintendent of Compulsory Education of the school board to operate an independent health department of his own. His motive is no doubt a laudable one, and if his efforts were guided by a moderate degree of professional intelligence and qualification for the work, they might be beneficial instead of detrimental."

**Physicians Register.**—The 1903 "Report on Medical Education" of the Illinois State Board of Health will be issued in about two weeks. This report includes an official register of physicians, corrected to September 14, 1903. Illinois physicians who desire a copy of the report should write to Dr. James A. Egan, secretary of the State Board of Health, Springfield.

**Appointment of Dr. Halstead.**—Dr. A. E. Halstead has been appointed attending surgeon to St. Luke's Hospital.

**University Buys Dental College.**—The absorption of the Chicago College of Dental Surgery by the University of Illinois has been consummated. Dr. Truman W. Brophy, the present Dean of the Dental College, will be retained in that capacity. The University has purchased the building and all the college property outright. It is said that 800 students are enrolled in the Dental College for the next term.

**Hospital for Contagious and Infectious Diseases.**—It is said, upon what appears to be reliable authority, that Rush Medical College has in contemplation the establishment of a hospital for the care of persons suffering with infectious diseases. This is to be one of the benefits, according to the present plan, which will come to Chicago as a result of the money set aside by John D. Rockefeller for the furtherance of the study of this line of medical

science. The need of such an institution is urgent. According to Chief Medical Inspector Heman Spalding of the City Health Department, there is insufficient accommodation for this class of patients, and as a result the infection is far greater than it should be. For years Dr. Spalding has urged the necessity of the establishment of such institutions, but the Council has failed to make appropriations because of the financial condition of the city. In only a few of the hospitals are the milder forms of contagious diseases treated. The Presbyterian Hospital has arrangements for the care of a few and the County Hospital cares for a limited number. Smallpox cases, however, are all cared for at the isolation hospital, but it is the other forms of infectious diseases that give the health department the greatest concern because of the lack of facilities to handle them. Physicians interested in this matter have urged the Rush College and University of Chicago authorities to agree to take the matter up and establish three hospitals for this class of patients, one in each of the divisions of the city where they would be easily accessible.

**Dr. Lynch Accepts a Position in the University of Chicago.**—Dr. Frank W. Lynch, associate in obstetrics at the Medical School of the Johns Hopkins University and for two years resident obstetrician in the hospital, has resigned to accept a position in the University of Chicago. Dr. Lynch took his collegiate degree at Adelbert College in 1895, and finished his medical education at Johns Hopkins. He graduated in 1899 and it is said that his promotion in university and hospital work since that time has been rapid.

## GENERAL.

**Library for the Blind.**—Under the auspices of the royal oculist Theodor, Duke of Bavaria, a committee has been formed for the purpose of creating a library for the blind in Hombourg.

**Prophylaxis of Leprosy in Indo-China.**—By a recent edict of the Governor General of Indo-China, lepers are forbidden to appear upon the public streets; and infraction of this law subjects them to arrest and transportation to the hospital for lepers on the island of Cu-lao-Rong.

**Oral Hygiene.**—The following action of the National Dental Association, at the recent meeting, held at Asheville, N. C., was taken: "Resolved, That it is the sense of the 'National Dental Association' that each Medical College in the United States should include in its curriculum a lectureship on 'Oral Hygiene, Prophylaxis, and Dental Pathology.'" The dental profession feels that with the introduction of the teaching of Oral Hygiene in the Public Schools, which they are striving to accomplish, and the cooperation of medical men who have been specially instructed on this subject, that a great stride will have been made toward the prevention of caries of the teeth, not to mention many other good results to the general system, which would surely follow a better care of the oral cavity.

**Diphtheria Antitoxin in London.**—By the use of the antitoxin treatment in diphtheria cases, of which there were 6,500 last year in the London hospitals, the death rate from the malady has been reduced in a few years from over 30 to 11 per cent.

**Medical Lecture Course.**—The directors of the Memphis Medical College have established a lectureship, named in memory of the late William E. Rogers, M.D., founder of that institution. The lectureship was established upon the suggestion of the faculty. Once during each session a lecture will be given by a specialist in some branch of medical science, at the invitation of the faculty. The first lecture will be given about the middle of November by Dr. Charles H. Hughes, of St. Louis.

**New Medical School Buildings at Chicago University.**—One of the most extensive real estate deals in the history of the city has practically been completed for the University of Chicago. The transactions involve the purchase of the entire south frontage of the Midway Plaisance between Cottage Grove and Madison avenue, at a total consideration estimated at $1,000,000 for the land and $450,000 for the buildings. The news of the extensive purchases confirms the reports which have circulated in university circles for some time that the medical school buildings are to be established on the Midway. Rush Medical College will form the nucleus of the institution, and it will be supplemented by the McCormick Memorial Institute for Infectious Diseases, for which extensive hospitals may be constructed on the "cottage" plan. Possibly the Chicago Polyclinic Hospital may be included also.

**Malarial Fever at Santiago.**—The unofficial reports current some time ago that yellow fever was prevalent in the vicinity of Santiago has led to special efforts on the part of the Public Health Service to get at the truth in regard to the epidemic in that quarter. The latest official reports received yesterday state that there is no reason for modifying the first diagnosis of the disease. It is malarial fever of a most pernicious character. Its worst extent appears in and around Daiquiri. The public health advices say that in some measure the facts bear out the unofficial statements that have been circulated regarding the disease. Acting Assistant Surgeon Wilson, at Santiago, under date of Sept. 5, describes the malady in detail. It attacks persons who have suffered several attacks of intermittent malarial fever. It is accompanied by vomiting, the body of the patient turns yellow, and cases not treated the first twelve hours are always fatal. The disease is spreading among the natives and all classes of residents. There have been a number of deaths. Yellow fever is officially reported at Monterey and Nuevo Laredo, Mexico. Great precautions against this disease are being taken along the Texas border. Acting Assistant Surgeon Hamilton, at Laredo, under orders from Surgeon General Wyman, is cooperating with the State health authorities. Tentage and camp equipage for 100 people have been sent to Laredo by Surgeon General Wyman.

**Bacteria as Purifiers of Sewage.**—At a recent meeting of the British Institute of Sanitary Engineers, held at Wolverhampton, England, a paper prepared by Dr. J. C. Thresh and Martin Priest, on the distribution of sewage on bacteria beds was the principal subject for discussion. The writers pointed out that it was now generally admitted that in the processes of sewage purification bacterial action was the most important factor and that the condition and quality of a sewage effluent would vary according to the different bacterial influences to which the sewage had been subjected. From the point of view of sewage purification, bacteria were divided into two classes, viz., anaerobes and aerobes, the anaerobes producing putrefaction fermentation, while the aerobes produced the true putrefaction, and it was the aerobic bacteria that they must chiefly endeavor to cultivate and employ in their sewage schemes. If bacterial treatment was the main factor in sewage purification, the proper utilization of the bacteria beds was the crux of the whole problem. The best means for the distribu-

tion of sewage on bacteria beds were: First, the so-called contact beds, in which the beds are filled with sewage, allowed to stand a certain time, then run off, and the beds allowed to aerate; second, distribution by means of alternating siphons, with or without arrangements for distributing the sewage over the whole surface of the beds; and, third, the continuous, or sprinkler system. Many installations of the contact system for some reasons had not proved satisfactory. As regards aeration, the contact beds compared very unfavorably with the sprinkler bed; because, while the contact bed is alternately filled and emptied, the continuous, or sprinkler, bed worked under constant aerobic conditions, with always an ample supply of oxygen. In conclusion, the writers pointed out that the bacterial system of purification merely improved the sewage from a chemical standpoint, and left it nearly as impure as before from the bacteriological standpoint, and possibly, therefore, quite as dangerous, so far as disseminating germs of typhoid fever, cholera, and other water-borne diseases were concerned.

**Purification of Water by Ozone.**—At Wiesbaden and Paderborn in Germany good results are said to have been obtained in the purification of water by the use of ozonized air, water of an inferior quality having been turned into very good drinking water. The plant at Wiesbaden contains 48 ozonizers, forming duplicate groups of twenty-four each. A set of eight ozonizers receives an alternating current of 8,000 volts from a step-up transformer. One pole of the apparatus consists of the cooling water of the glass tube, and is earthed, while the other pole, connected to the transformers, is placed in an inaccessible position, and therefore causes no danger to the attendant. The ozonizing tubes are enclosed in a cast-iron case consisting of three parts: (1) A completely closed central portion, into which are firmly screwed the eight ozone tubes; (2) an upper part, acting as a reservoir and distributor of the air, and (3) a lower part, forming the ozone-collecting chamber. In the upper chamber, removed from all possible touch of the attendant, are fixed the terminals from the transformers. On the floor of the lower compartment are placed the high potential cylinders with their insulating glass rods, and in addition an automatic device to prevent a short-circuit through any leakage of the cooling water. This consists simply of a strip of filter paper stretched across a metal spring. If the filter paper gets moist it tears, the spring opens out and automatically puts that particular ozonizer out of use.

**Medical Service in Battle.**—The tactical lessons taught by the Spanish-American and the Boer wars have been much discussed, and these have suggested another question intimately connected with the tactics of the situation, and the solution of which is entirely dependent on these tactics, namely:

"What," writes the *Sun*, "have these wars taught as regards the medical service on the battlefield? In view of this intimate connection between the two, it is evident that the medical service should profit by the lessons learned in tactics, and regulate its work on the battlefield accordingly. The battles before Santiago, fought with small caliber rifles and smokeless powder, furnish no connected data for practical use in making tactical deductions; all considerations of the subject were more or less theoretical. But the Spanish-American, and more particularly the South African war helped to solve the problem. The American army was the first to make an attack on a battlefield which had no curtain of smoke to furnish cover or to mark the enemy's line and to advance against small caliber repeating rifles. The campaign was short, however, and the conditions limited, consequently the Spanish-American war furnished merely the initial data, while the South African war, with its great numbers, its variety of conditions and its examples of important battles, furnished a mass of material for the new tactics.

"A study of the experiences in these two wars shows that there are three principles of tactics developed by them which bear on the medical service in the field: 1. The movements of the attack have become much slower. 2. To obtain superiority of fire it has become necessary to remain much longer in the firing positions. 3. The battle begins at much longer ranges, and serious wounds are produced at far greater distances than formerly. All these affect the location of field hospitals, etc., and the work of the medical officer on the battlefield at various stages of the battle. The first is explained by the accuracy of the modern arm, the lack of cover to the attack, formerly furnished by the cloud of smoke, but above all by the invisibility of the enemy. As a British officer graphically expressed it: 'In a modern battle what affects the assailant most seriously is the emptiness of the battlefield.' The second principle results from the first, but has its own explanation, too. Superiority of fire depends on the relative effects on both sides, and, in spite of all improvements in firearms, it takes much longer now to gain superiority of fire, because of the great losses in the open; consequently, the attacking force must stay longer in its successive firing positions (under cover) before it can hope to advance to the next one. What requires but a few minutes in peace maneuvers will demand hours in time of war. The third principle results from the greater power of the modern arm. The successive firing positions will be the places where the wounded will accumulate, and there the surgeons will be particularly needed. But they will be in demand even at great distances, for target practice experience shows that at 1,000 yards a line of skirmishers can in five minutes put 35 per cent. of a similar line out of action, and, although the losses at this range, as shown in the last two wars, were less than this, they were still serious. As the ranges decrease the destructive effects rapidly increase. At 800 yards the cranium is perforated; at 500 yards the long bones are broken into pieces as small as a pea, and the adjacent muscles are torn away; and at 400 yards blood vessels are pierced or particles are torn from them, causing grave hemorrhages, often proving mortal. To avoid the moral effect of so many wounded the medical attendants must advance with the line to give aid. They can no longer remain beyond the zone of fire, but must go where they are needed. But it is evident that this corps cannot perform its work on the line of skirmishers, except during the pauses in the battle or when the objective of attack is changed. The troops themselves must therefore act on the line of skirmishers while the firing is going on, and for this purpose they are provided with their first aid packages. If any cover is available near the line the wounded will instinctively seek it, and there, too, the medical corps must come into action. These improvised stations can render provisional service, but they must be in communication with the field hospitals in rear, and the latter must be carefully selected for that reason. Cover is the main thing at first, and water, straw or bedding are secondary con-

siderations. In the Franco-Prussian war such cover was often found at 600 yards behind the principal firing line, but the modern gun has a much flatter trajectory than the needle gun of that day, consequently the protecting cover can be much lower. At 600 yards the projectile rises but 8 feet above the line of sight, and at 1,000 yards only 33 feet. For these reasons medical officers must be carefully trained in time of peace promptly to select proper cover for their stations near the troops, and must be in touch with the tactical situation in war in order to effect this intelligently. The slightly wounded must be rapidly transported to the rear, for it is a well-known fact that many of the wounds of the small caliber bullet heal rapidly; therefore the enemy will make every effort to capture the stations where they accumulate, in order to prevent their returning to the ranks in the near future. It is evident, therefore, that under the new conditions the medical officers must acquire a general knowledge of tactics, and in a battle must be informed of the general tactical situation, and they must also familiarize themselves with the proper use of cover. Their stations must be close up to the firing line and must be moved to the front continually in order to take proper advantage of the pauses in the battle. The most advanced stations will be improvised and will be determined by the troops themselves—the dead angles or places under slight cover, to which the wounded have crawled of their own accord. The others must be selected with reference to cover alone, and must be connected with the field hospitals arranged in rear and out of the limits of the zone of fire."

**The International Association of the Medical Press.**—A meeting of the Committee of the International Association of the Medical Press, writes the *British Medical Journal*, was held at Brussels on September 1, in one of the Committee rooms of the Belgian House of Representatives. The following countries were represented: Spain, Dr. Cortezo (President) and Dr. Monmeneu; France, Drs. Granjux and Blondel; Belgium, Dr. Déjace; Norway, Dr. Aaser; Denmark, Dr. Caroë; Portugal, Dr. Silva Carvalho; United Kingdom, Dr. Dawson Williams and Mr. Adolphe Smith. Regulations for the conduct of the business of the Committee were adopted, and it was resolved to bring the existence and aims of the Association under the notice of the editors of the principal medical journals in America, North and South. Applications were received from the directors of medical journals in Holland and Hungary, and the Committee decided to invite these gentlemen to take steps for the formation of national associations. The question whether a congress of the medical press should be held in Lisbon immediately before the International Medical Congress to be held there in 1905, or whether the Congress should be replaced by a general meeting of the International Association was considered, but a decision deferred until the next meeting of the Committee.

**Obituary.**—Dr. S. S. H. Stout is dead at Clarenden, Texas, at the age of eighty-two years. He was a native of Tennessee and served through the Civil War as Director of the Medical Department of the Confederate Army. Dr. Stout was graduated from the University of Nashville in 1842 with the degree of A.M., and in 1848 from the University of Pennsylvania with the degree of M.D. The honorary degree of LL.D. was conferred upon him at the University of Nashville in 1885.

Dr. Egbert Guernsey, the eminent homeopathic physician of New York, who died at his summer home in Fishkill Landing, N. Y., last Saturday, was born in Litchfield County, Conn., on July 8, 1823. He was educated in Phillips Academy, Andover, the Yale Scientific School, and the Medical College of the University of the City of New York, from which he was graduated with the degree of M.D. in 1846. Instead of beginning practice, he started the newspaper now known as the Brooklyn *Daily Times* and then as the *Williamsburgh Times*. While editing that paper he prepared two school histories of the United States, which were widely adopted as text-books. In the spring of 1849 he was appointed City Physician of Williamsburgh, and then began to give his attention exclusively to his profession. In 1850 he established his office in this city. Dr. Guernsey did a wide work in the literature of his profession. In 1855 he published "Domestic Practice," which has passed through eleven editions. He was associated with Dr. A. Gerald Hall in the publication of "Jahr's Manual," and was for years editor-in-chief of the New York *Medical News-Times*, which he founded in 1872. In 1870 he organized the Western Dispensary, which has since been connected with the Hahnemann Hospital, which he also helped to organize. He was also one of the prime movers in the organization of the Metropolitan Hospital, on Blackwell's Island, and gave constant service in the development of that institution. It was through his instrumentality that the old Inebriate Asylum on Ward's Island was converted into the Manhattan State Hospital under the direction of the Commissioners of Charity and Correction in 1877, and he was for many years the President of the hospital. He was for a long time trustee and at one time Vice-President of the State Insane Asylum at Middletown, N. Y., and had been President of both the county and State medical societies. Dr. Guernsey was one of the founders of the Union League Club, and at the time of his death was a member of that club; the Sons of the Revolution, the National Academy of Design, the New England Society, and the New York Historical Society, besides a number of medical and philanthropic organizations.

## CORRESPONDENCE.

### DR. ADAMI AND THE AMERICAN CONGRESS OF TUBERCULOSIS (CLARK BELL).

*To the Editor of the* MEDICAL NEWS:

SIR: Upon my return from abroad a few days ago, I learned for the first time that I had been announced as one of the Honorary Presidents of the American Congress of Tuberculosis (Clark Bell). This announcement had been made without my knowledge and had been communicated to the public press before ever I had been approached in the matter. After that communication (June 11) I find that I was addressed upon the subject (June 12). The notice, which I have before me, is in the form of a copygraph letter upon the flimsiest of yellow paper, dirty and badly folded, and is not to the effect that I had been appointed Honorary President, but merely a curt reference to an enclosed list of officers elected at a recent session, ending with the expression of the hope that I would accept. The enclosure consists of two columns cut out of the New York *Daily Tribune* which, it is true, contains my name (misspelled) on the list of Honorary Presidents. I am not in the least surprised that my First Assistant mistook the communication for a second-class adver-

tisement or something of the kind and never realized that it was matter which should be forwarded.

Under no circumstances would I have consented to allow my name to be connected with the organization in question. The employment of the name as that of an Honorary President is and has been wholly unauthorized and I have written asking that it be withdrawn.

I am, Sir,
Yours faithfully,
J. GEORGE ADAMI.

Pathological Laboratory, McGill University, Montreal, Sept. 18, 1903.

## SOCIETY PROCEEDINGS.

### THE NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting held Thursday, May 21, 1903.*

The Vice-President, Charles L. Dana, M. D., in the Chair.

**Symposium on Puerperal Infection.**—The scientific business of the evening consisted of a series of papers read under the auspices of the Section on Obstetrics and Gynecology. The subject was a symposium on puerperal infection. The first paper consisted of a historical review of the subject by Dr. Brooks H. Wells.

**Amelioration of Puerperal Conditions.**—This paper will be published in a subsequent issue of the MEDICAL NEWS.

**Pathology and Prophylaxis.**—Dr. J. Clifton Edgar presented a paper upon this subject, which will be published in the MEDICAL NEWS shortly.

**Intravenous Antisepsis.**—Dr. Charles C. Barrows reported a series of cases of puerperal fever successfully treated by the injection of one-half liter to a liter of a 1-5,000 solution of formaldehyde. The cases originally reported by him have given rise to an extensive literature of the subject and this he reviewed to some extent. Drs. Park and Payne, of the New York Board of Health, have taken up the same subject experimentally on animals, and have shown that injections of formaldehyde are not curative when there are virulent streptococci in the circulation of rabbits. Dr. Barrows pointed out that rabbits were bad subjects for such experiments, since they did not, because of idiosyncracy, stand formaldehyle injections well, and besides, were especially susceptible to septic conditions. While Drs. Park and Payne's observations deserve the utmost consideration they must be judged only on their merits, and it must be borne in mind that there is no mention of the time allowed to elapse between the injection of virulent streptococci and the use of the formaldehyde solution.

**Exaggeration of Danger.**—A number of personal observations made by physicians shows that the introduction of formaldehyde solution into the venous circulation is not likely to cause serious symptoms. McGuire's experiments, done in London, particularly show that large amounts of formaldehyde may be taken into the system without danger. The cyanosis and syncope which have been reported after some injections may occur after intravenous salt infusion, and are not necessarily due to the formaldehyde. Too many observations have been made now for the objection of danger to have any great weight on the subject.

**Technic of Method.**—The median basilic or cephalic veins are snipped with a scissors in order to make an easy opening for the canula. A longitudinal opening made with a knife is not nearly so suitable for the purpose. Care must be exercised that the canula is not introduced into the sheath of the vein, but this accidental misplacement will be followed immediately by the production of a tumor at the site, and then can be corrected. The solution must be introduced slowly, and the patient's condition should be watched carefully, so as to avoid the production of syncope or any disturbance of the general condition.

**Illustrative Cases.**—Dr. Barrows reported some 14 cases from the practice of friends and brother physicians, an accident to his patella some three months ago having made it impossible for him to continue his observations with regard to it. In one case there was expulsive vomiting, a tender tympanitic abdomen, a temperature of 105° F., with a pulse of 150. This case looked surely fatal, yet after the injection of formaldehyde of 1-5,000, the temperature promptly dropped, and the patient continued to convalesce up to a perfect recovery. In another case a rapid rise of temperature took place on the sixth day after labor, which fell after curettement, but only to rise again this time to 105° F. An intraveneous injection with formaldehyde was given 1-4,000, and this was followed by a chill and by some cyanosis. The temperature fell, however, and rose again the next day to above 105° F., when another injection was given, followed by a drop of temperature without a subsequent rise. In certain cases a solution of formaldehyde stronger than 1-5,000 and even as strong as 1-2,500 was employed with good result. In several cases that yielded very nicely to formaldehyde injections, antistreptococcus serum had been faithfully tried without effect.

**Specific Action of Formaldehyde Solution.**—In a controlled case of puerperal septic fever, in which, instead of formaldehyde solution, normal salt solution was employed, the result was fatal and without the drop in temperature, which so invariably accompanies the injection of the formaldehyde solution. Sajous, in his recent book on the therapeutic action of glandular extracts, suggests that formaldehyde is a stimulant to the adrenal system. He quotes Dr. Barrows' cases and considers that the stimulation of the adrenals causes a distinct and demonstrable rise in the bacteriolytic action of the blood serum and other fluids within the body. To this, in Sajous' opinion, are to be attributed the good results obtained from the formaldehyde injections.

**Frequency of Puerperal Fever.**—Dr. William R. Pryor said that in spite of the discoveries in bacteriology that had made very clear just what the causes of puerperal fever are, quite as many women perish from the disease now as before its pathogenesis was known. It is clear that the affection is really a form of a lymphangitis, and that death is not due so much to the presence of germs in the uterus as to their absorption into the system when they occur in the heart, and even the brain and the kidneys. It is not so much the changes in the blood either that cause the fatality of the disease, and it is never the local lesions. The local lesions may be comparatively insignificant. If there is to be any remedy for the affection it will be found in some substance that will act as an antiseptic, follow the germs and their toxic secretions into the lymphatics and there neutralize them by direct destructive action.

**Bacteria in the Abdominal Cavity.**—By a series of observations made in cases of severe infection Dr. Pryor has succeeded in showing that streptococci are practically always free in the abdominal cavity. In certain cases where there were symptoms of beginning peritonitis in the pelvis Dr. Pryor has opened up and packed the posterior cul-de-sac with iodoform gauze. After such treatment no cocci were found to be present on the second or third dressing, though colon bacilli had found their way through the intestinal walls and were practically always present. The setting free

of iodine in the presence of the tissues, as happens when iodoform is brought in contact with a lacerated surface, or with a serous membrane, is the best antiseptic action that can be obtained, and brings about a rapid drop of temperature and pulse. The evidence of the absorption of iodine is to be found in its presence in the urine, which may usually be demonstrated in five hours and sometimes even in two.

**Danger of Curettage.**—Dr. Pryor thinks that an immense amount of mischief has been done by the use of the curette. Lymphatics that have been closed by nature's processes and are effectually preventing the progress of the septic condition are rudely opened up and made patulous by means of the sharp curette, and as the infected material is not entirely removed this proves a new nidus for infection for further septic processes.

**Results with Iodoform.**—Dr. Pryor has treated some 37 cases with iodine, with but one death. It is important that iodism should be secured, but this may be accomplished effectively even by the use of liberal amounts of iodoform ointment applied externally. Once iodism is obtained, not only is the mortality lessened, but the morbidity decreases very materially, and the convalescence of these cases, usually so tedious and so prolonged, with so many complications and sequelæ, is over in a short time, and patients promptly recover their normal health.

**Condemnation of Curettage.**—Dr. Herman J. Boldt, in discussing the operative treatment of puerperal fever, said that undoubtedly curetting is often a mistake and cannot be too severely condemned. It is only when the condition is due to saprophytic organisms, and not to pyogenic organisms, that instrumental cleaning out of the uterus is justified. On the other hand, repeated intra-uterine irrigation may be easily carried to such an extent as to add distinctly to the danger in milder cases of puerperal sepsis, without any additional safeguard being added adequate to the risk entailed. Minor surgical procedures, which used to be considered favorable in these cases, are now practically abandoned.

**Uterine Extirpation.**—Extirpation of the uterus is so serious a remedy that it can only be thought of in cases of puerperal sepsis, when there is reasonable assurance that the septic condition was limited to the uterus, and when treatment of any other kind has proved to be of no avail. Only in the gravest forms of the affection has it been practised and even then it has proved to give very little satisfaction. Whenever bacteria could be demonstrated in the circulation, the operation has always failed. A number of patients have died after the operation, even when the septic condition seemed limited to the uterus, and when no bacteria could be demonstrated in the blood. The time required for the operation must not be permitted to stand as an objection against it since, under favorable circumstances, the uterus may be extirpated in ten minutes and at times the operation has even been completed in six minutes.

**Bacterial Diagnosis and Its Shortcomings.**—At the present time nothing is more needed than some rapid method of deciding that bacteria are surely present in the blood. Under present conditions of knowledge and technic, at least twenty-four hours is required in order to demonstrate by cultures whatever bacteria may be in the circulation. This is entirely too long, and some method of deciding so important a question, even by a few hours, must be found, if bacteriological diagnosis is to be of real assistance to surgery. There remains the question of the abdominal or vaginal route for operation. The latter should be chosen unless the uterus, as is often the case, proves to be too large for removal in this way. Of course, precautions must be taken that in the removal of the uterus infective material is not spread over other portions of the pelvis. If the broad ligaments are affected, then the operation should be done through the abdomen. Trendelenburg has reported some good results by following this method. If the uterus is large and boggy, then, as a rule, removal should not be undertaken, but the decision must ultimately depend upon the patient's condition.

**Not Treatment but Prophylaxis.**—In opening the discussion, Dr. Egbert Grandin said that he doubts if there has been any sure advance in recent years in the treatment of puerperal infection. Whatever improvement has come has been in the matter of prophylaxis. Otherwise, for twenty-five years, obstetrics has been at a standstill. This has not prevented surgical interference of the most varied kind, however, and undoubtedly harm rather than good has been done, as a rule. Those who have been readiest to interfere actively for the treatment of the condition have been least careful to differentiate the various types of puerperal infection before beginning treatment. The putrefactive varieties of puerperal sepsis are rarely fatal unless the pathological processes in the uterus are needlessly interfered with, nature's protective mechanism broken down, and the resistive vitality of the patient lowered by uncalled for remedial measures.

**Danger of the Curette.**—In 1886 Dr. Grandin read a paper recommending the use of the curette for certain conditions of puerperal infection. Many editors commented upon it, and portions of it, at least, were printed in many parts of the country, evidently attracting a great deal of attention. Undoubtedly, it has been a source of much more harm than good. In the case of retained remnants of the placenta and secundines the curette is not nearly as useful as the finger. The use of the curette opens the lymphatics, brings about the diffusion of septic material, and makes the cure of the condition impossible. The hand will do all that is needed in these cases and without any of the risk of causing damage almost inevitably incident to the employment of the curette. A good general rule in the treatment of these infections is avoidance of local treatment. The less that is done locally the better. The methods suggested by Drs. Barrows and Pryor, by which an effort is made to have an antiseptic follow the infected material into the tissues or neutralize it in the circulation, is undoubtedly the principle of rational therapeutics that will eventually prevail in this matter. The results obtained by them are very encouraging. Yet it must not be forgotten that the severest and most hopeless-looking cases of puerperal sepsis sometimes get better unexpectedly, without the employment of either of the methods suggested, and, in fact, without any treatment at all.

**Operative Interference.**—Whenever there is pus present in the pelvis it should be evacuated. This is the simple rule of all rational surgery. Beyond this, however, operative intervention is almost sure to do harm rather than good. Dr. Grandin confesses to being guilty of having done hysterectomy twice in puerperal sepsis. To be of any avail this should be done very early. As a matter of fact, the time for doing hysterectomy when there is hope of its being successful is so early in a case that there is very little prospect of the operation ever being really undertaken in time. Surgery in puerperal fever has been entirely too radical and too ineffective. What is needed is some agent, such as Dr. Barrows and Dr. Pryor are making their observations with, that will, if possible, follow the streptococci in its invading course to the lungs, the brain, the heart, and the kidneys of the patient.

**Prognosis not Absolute.**—Dr. Henry C. Coe said there is no absolute prognosis of any individual case of

puerperal fever. At Bellevue, as is well known, the worst looking cases, that apparently have come in moribund, sometimes unexpectedly recover. Dr. Coe has seen ordinary intravenous salt solution injections given to a moribund patient, as a last resort, produce a drop of temperature from 104° to 98° F., without producing a chill. The temperature remained down for many hours, and was again lowered by salt solution injection. Hysterectomy is in theory indicated in cases where the localization of the infection is limited to the uterine tissues, but it is practically impossible to obtain an indication for the operation early enough in such cases to reduce the theory to successful practice.

**Prompt Treatment.**—Dr. Simon Marks said that the most important element for the successful treatment of puerperal fever is undoubtedly its early recognition. When the practitioner finds that the temperature has gone up in a puerperal patient, he hesitates to admit that there can be any puerperal infection. Other sources of fever are thought of first and treatment for supposed infection is allowed to drag along for some time. The practitioner hesitates to ask for consultation and the result is that when a consultant eventually is called the woman is usually moribund. There is no doubt that there will be some morbidity from puerperal infection, even in the best hands. If the practitioner is ready to admit this, cases will not be neglected until it is too late. Every case that presents a temperature above 100° F. should be considered serious, and if the uterus is cleared out sufficiently early there will often be an end of the danger.

**Too Much Deprecation of Curette.**—Dr. Marks considers that just as there was an exaggeration in the use of the curette, so now the reaction against its use is going too far. Personally, Dr. Marks does not fear the use of the curette, and considers that in expert hands it is much safer than the finger. Often the cervix is so closed that the finger cannot be inserted, or is not able to reach portions of the cornua of the uterus, which are readily reached by the curette. At times the localization of infectious material seems to be entirely on the inner surface of the uterus where it can be removed. If promptly treated, prophylaxis is, of course, much more important than treatment. Good, ordinary cleansing of the hands of the obstetrician is, however, almost more important than any of the more recently introduced and highly praised methods of aseptics. The use of gloves, for instance, has not given much difference to the morbidity of puerperal patients, as compared with the best results obtained before their use. In some 60 cases delivered with gloves there were some 24 per cent. morbidity.

**Old-time Treatment.**—Dr. S. W. S. Toms, of Nyack, said that there has been very little improvement by the introduction of new-fangled methods of treatment. At Bellevue, in the old days, opium was used freely and the statistics of recovery were quite as good as at the present time. After all, the patient's restfulness in these cases prevents the dissemination of infectious material very probably, and increases vital resistance by lessening fear and anxiety as to the result.

---

## MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

*Fifty-third Annual Meeting held at York, September 22, 23 and 24, 1903.*

FIRST DAY—SEPTEMBER 22.

The Society was called to order by the President, Dr. William M. Welch, of Philadelphia. Rev. E. T. Jeffers offered prayer. Hon. M. B. Gibson, Mayor of York, then welcomed the members of the Society to the city. He dwelt on the early history of the town, there now being manufactories instead of the historic buildings of the Revolutionary period when the Continental Congress met on the site of what is now the Colonial Hotel, the headquarters of the Society. The city now has absolutely pure, filtered water, and is soon to instal a sanitary sewage system at a cost of $400,000.

A brief address of welcome was then extended by Dr. N. C. Wallace, President of the York County Medical Society.

The presentation of the program by Dr. I. C. Gable revealed several departures from those of previous meetings. This was the first meeting of the Society held under the new rules, which provide for the transaction of business by an executive council. Advantage was also taken of a recent by-law to hold Wednesday's and Thursday's morning sessions in two sections, this being necessitated by the large number, more than 80, of papers presented. The annual addresses were all given on Tuesday afternoon.

Dr. J. N. McCormick, of Bowling Green, Ky., representing the American Medical Association, was given the privilege of the floor and made a very strong appeal for a more thorough organization of the profession. Up to this time only the surface has been touched. There are probably 120,000 physicians in the United States, and only 30,000 of them are members of any society. A united profession is hindered by the petty jealousies and constant warring of neighboring practitioners, doctors being at peace with every one except their own clan. Malpractice suits are aided in this way and ofttimes necessary surgical work is not undertaken because of fear of the outcome and the stock made of it by fellow physicians. Speaking of handling men who drift into bad methods, Dr. McCormick told of one who, after trying every other means, they made president of a county society. This put him on his mettle and he finally became a respectable practitioner. A valuable feature of organization is the power it gives the older men to watch over the younger ones.

The remainder of the forenoon session was devoted to the reports of officers, committees, etc. The Secretary reported a membership of 3,665, a gain during the year of 145.

**Address in Surgery: The Individual Equation of the Patient in Surgical Operations.**—Dr. W. L. Estes, of South Bethlehem, said that operations themselves give very little concern these days, but occasionally a death occurs when an apparently ideal operation has been performed. Other patients, though outwardly less favorable, get well. These occurrences suggest that there is an average vitality among patients and that this is determined by several factors. These should be carefully studied. Among the conditions that affect the reaction of the individual to traumatism are heredity, environment and habit and the physical condition of the patient. The question of heredity is a complex one as probably no disease other than syphilis is directly transmitted to offspring. But tendencies are transmitted, a peculiarity of cells, a chemical individuality, so to speak. This makes for or against vitality of the patient. Dyscrasias are thus transmitted and low resistances of cells to noxious influences or low power to produce antitoxins result in deaths from low grades of sepsis. Under environment Dr. Estes made a point that is rather opposed to previous beliefs. This was that the baleful effects of bad sanitation are by no means confined to the city and town. Conversely, he states that town or city-bred people stand operations better than do the average farmer. The fresh air and plentiful food of the latter are to a large extent nullified by overcrowding in sleeping apartments and by eating poorly cooked food. The physical condition of

the patient is often the turning point in a case and a thorough examination by the surgeon himself or by a competent aide should be insisted upon in every case. Taking physical examination to include the urine, it is of greater diagnostic value than laboratory methods. But the two should be combined.

**Address in Obstetrics: X-ray Treatment of Uterine Cancer and the Etiology of Eclampsia.**—Dr. John G. Clark, of Philadelphia, reviewed the above subjects. He spoke of the mortality from uterine cancer and the efforts being made in the line of earlier diagnosis. But 50 per cent. of the cases, as seen in a clinic, are already inoperable. Any method that promises results in these cases should be given a thorough trial. The action of the X-ray is still problematical, though it is probable that the healing effect is more in the line of stimulation. No one person has had sufficient experience to be an authority on the effect of X-ray treatment and the opinions of two classes must be combined—those that are skilled in the application of the X-ray and those who observe the preceding and subsequent history of the patient. Dr. Clark has had a limited personal experience in the use of the X-ray, but from it and from a careful review of the literature he draws the following conclusions: (1) No operable case of cancer of the uterus should be temporized by the use of the X-ray; (2) local therapeutic agents are practically valueless; (3) even in inoperable cases there is a very remote hope of cure and there is almost sure to be relief of pain; (4) the X-ray is on a sufficient basis and promises enough that this method of treatment should be thoroughly investigated. The principal point brought out in regard to eclampsia was that recent investigations throw doubt on its origin in the kidney alone, acting rather as a general poison.

**Address in Hygiene and State Medicine.**—Dr. Seneca Egbert, of Philadelphia, pointed out some of the results that have already accrued from recent investigations in these lines and gave a forecast of what may be expected in the future. The paper was largely a statistical collection of facts regarding the lowered mortality of the present as compared with the preceding decade. The agencies of preventive medicine have very largely benefited the people; especially those of cities. Philadelphia and Pittsburg do not show the decreased death rate they should and have been especially negligent in vaccination and the prevention of typhoid fever. The need of educating all the people in sanitation is paramount. State Boards of Health need the unanimous support of the public. The vital statistics recently asked by the government should be rigidly supplied. School children should be taught far more than at present concerning sanitation, quarantine, heredity, environment, need of fresh air, parks, proper occupations, etc. The course in physiology and hygiene should continue until they leave school.

**Address in Neurology: Insanity.**—Dr. Charles B. Mayberry, of Retreat, criticised the treatment of the insane under present methods. All varieties are placed together, though he has never seen good results from contact of patients. The family physician has a great part in preventing insanity. He it is who watches over children during their development and sees the adult before the outbreak of insanity. A history of insanity in the family should cause particular attention to the child or even adult during critical periods of its life. Of 600 admitted cases there was a family history of insanity in 163. Danger signals should be recognized. The present condition in state hospitals tends to prolong attacks of the condition. Dr. Mayberry would suggest: (1) An extended course of instruction in clinical and didactic psychiatry in our medical schools; (2) the erection of small psychopathic hospitals throughout the state for the treatment of acute, curable cases. Pennsylvania would need six of these; (3) with each one of these should be maintained an outpatient department, in order to keep under observation for one year every patient that was discharged; (4) the establishment of a central pathological laboratory for the further study of the condition. It is being more and more recognized that the pathology of insanity is the pathology of the entire body.

**Address in Ophthalmology.**—Dr. E. B. Heckel, of Pittsburg, traced some of the history of this branch which is almost as old as medicine itself. Ophthalmologists have been accused of using the same old drugs—mercury, silver nitrate, and atropine. This is true, but each has undergone marked improvement in the method of use. American ophthalmologists are considered to be the equal, and in some respects, the superior of those of Europe. The relation of the ophthalmologist to the profession and to the laity was discussed. His position in the profession is secure. His standing among the laity will largely depend upon the actions of the general practitioner, as to whether he sends patients to reputable or incompetent men.

**Address in Medicine: Treatment of Pulmonary Tuberculosis at White Haven.**—Dr. H. M. Neale, of Upper Lehigh, gave a description of the methods of feeding, exercise, rest, sun baths, etc., as employed at the White Haven Sanatorium. These are essentially the same as those which appeared in the MEDICAL NEWS a few weeks since.

**Is There a Medical Profession?**—Dr. T. D. Davis, of Pittsburg, said that this question seemed unnecessary, but furnished much evidence to prove that it is a pertinent one. He referred particularly to the lack of organization, although there are societies of all sorts. An authoratative body is yet lacking.

**The Importance and Necessity of Industrial Hospitals.**—Dr. W. B. Lowman, of Johnstown, after an experience of sixteen years with such an institution, accords it hearty praise. By industrial hospitals he means those connected with manufacturing or industrial establishments containing large numbers of workmen that are liable to injury. They are intended to receive accident cases only. The one in question is maintained by the Cambria Iron Company. At first it had but 12 beds and during the first year it was used for 32 in-patients and 363 ambulance cases. There are now 40 beds and last year there were treated 604 in-patients and 3,104 ambulance cases. There are two points in its favor—it is just and humane to the men, and it pays as a business investment. The sooner accident cases are attended to the better for every one concerned. At the hospital everything needed in an operation is at hand. At a private house nothing is ready for the surgeon. Employees come to entertain a better opinion of their employer and thus is brought about a better understanding between capital and labor. Litigation is diminished. To organize these hospitals the business side of the question must be presented to the corporation. The humanitarian side has been too much emphasized. The average cost of the hospital mentioned has been 85 cents per patient per day.

**The Medical Expert Witness.**—Dr. G. W. Wagoner, of Johnstown, spoke of the difficulties besetting the expert medical witness and offered pertinent advice concerning his actions. The difference between a common and an expert witness is a great one, yet attorneys deny that experts are advisers to the courts. Hired experts give conflicting testimony and the truth is covered over, instead of being made clear. The jury throws all of the testimony out and experts are discredited. Another difficulty is that the courts do not distinguish between *physicians* as experts. Often no

classification according to school, length of time since graduation, etc., is made.

**Further Reflections on State Medical Board Examinations.**—In answer to criticisms, Dr. A. O. J. Kelly, of Philadelphia, reaffirmed his opinions as embodied in an article read at the meeting of 1902.

(To be Continued.)

## SPECIAL ARTICLE.

### BYWAYS OF MEDICAL LITERATURE.—XVII.

#### PULSE BEATS AND MUSICAL RHYTHM.

In the *Popular Science Monthly* for September there is an article on Pulse and Rhythm, by Mary Hallock, that is calculated to be of great interest to physicians. Miss Hallock calls attention to the fact that from the earliest times there has been an impression abroad in many minds that rhythm in music was somehow associated with the pulse beat of ordinary human existence. This idea has been repudiated as visionary, yet there would seem to be good basis for the idea in all kinds of music, the ultra-classical, as well as the most familiar melody, the most solemn church chants as well as the hackneyed rag-time.

The majority of Beethoven's sonatas, for instance, are written to a metronomic notation of 72 to 76 beats to the minute, almost exactly the average number of the human pulse in health. All of them are within the limits of pulse variation, written to metronomic notation of from 58 to 81, being exactly the limits of the pulse during the physiological rhythm of daily metabolism. Seventeen bandmasters, consulted as to the rhythm to which they kept their music, answered from 64 to 72 beats per minute, which corresponds closely to the average pulse rate and bears a definite relation to the fact that this is about the number of steps per minute that bodies of men take with least fatigue and with the greatest satisfaction. Both facts may then be unconscious tributes to the influence of the cardiac rhythm within making itself felt in brain processes.

The musically inclined will find by consulting their pulse beats that a whistling street-urchin or a jangling hotel piano is giving forth a succession of sounds, the emphatic notes of which correspond very closely with the pulse beats. The doxology and "Yankee Doodle," far apart as they would seem to be in musical and ethical relations, have the physical quality in common that the successive beats in the music follow one another at intervals of a second, thus corresponding to the pulse rate. On the other hand Chopin, of nervous temperament and suffering during the period of his greatest productivity in music from the slowly progressing pulmonary tuberculosis that eventually carried him off, wrote his great set pieces to a metronome running at over 80 per minute—thus reflecting perhaps his physical condition and the pulse beat in his cerebral arteries, which, in his condition, was constantly higher than normal.

Miss Hallock suggests that this correspondence of pulse beat and music rhythm may be really a case of cause and effect. The objection, of course, might be made that any such influence is entirely unrecognized, but it is well-known that factors, even of importance, constantly acting upon the senses may come to be neglected and the same thing may easily happen with regard to the arterial wave and its influence on the brain, yet the result of that influence be clearly manifest in some direct or indirect outcome of brain activity that occurs as a consequence. The whole question is one of those highly interesting physiologico-psychological problems that deserves to be studied more carefully than in the past, for it has within it the promise of interesting relationships hitherto unsuspected.

#### THE PHYSICIAN IN LITERATURE.

A number of young physicians have recently attracted attention by their success in the field of literature. One of the latest to come to the front is Dr. Archibald Stodart-Walker, rather well-known before this for his valuable investigation in psychology and neurology, published under the title of "Researches in the Reaction Time of Touch, Light and Thought" and his monographs on "Hysteria in the Male," "Hypnotism" and "Crime Habit and Control." It seems to be quite the proper thing for neurologists and psychiatrists to dabble in literature, and we have, of course, some distinguished examples on this side of the water. Dr. Stodart-Walker's first venture came many years ago when he was only a little over ten years of age, yet he assisted in editing and wrote, it is said, a number of the verses in the Scottish Students' Song Book. In recent years the doctor has been rather widely known to the literary world because to him was committed the preparation for publication of the Journal Letters and other remains of his gifted uncle, the well-known professor, John Stuart Blackie, of the University of Edinburgh.

Dr. Stodart-Walker's venture into the realm of pure literature is a book with the rather striking title "A Struggle for Success." The author describes it as a study in Social Compromise, Expediency and Adaptability. A recent critic in the Edinburgh *Scotsman* describes the book as striking but also alarming, in that the Doctor states so forcibly certain of the social tendencies of the time. Some of the Doctor's views in social affairs are conventional to a degree seldom expressed in print. This is especially true of his attitude as regards morals and marriage, and his description of hypocrisy of the present generation with regard to many of the things it is supposed to hold dear while nothing really counts for it in the struggle for success except the getting there at any cost. It seems not unlikely that Dr. Stodart-Walker's position as a neurologist and the closeness of his association with a large number of people because of his professional career has given him an insight into social conditions much farther below the surface than is possible for the ordinary man whose occupations rather take him away from the opportunities for such study.

Among the other distinguished Edinburgh authors of to-day is the daughter of the distinguished Sir James Y. Simpson of chloroform fame. Miss Eve Blantyre Simpson's name will be familiar to not a few American readers because of her book "Robert Louis Stevenson's Edinburgh Days." Miss Simpson is a great lover of the country and is devoted to animals, one of her most read books being "Dogs of Other Days." She has inherited not a little of her father's taste for scientific pursuits and her literary work has taken the form of studies in folk lore in the historical traditions and legends of Scotland and on these subjects she is a frequent contributor to the *Scotsman, Blackwood's* and *Chambers'* magazines.

A very recently published novel, by a medical author, that is attracting no little attention having, it is said, gone into its second edition before the announced date of its publication, is "The Third Degree," by Dr. Charles Ross Jackson, of New York city, though there is no evidence on the title page to indicate the fact that the author is a member of the profession. Novel readers who keep up to the times in fiction, and hard enough it is, will recall with pleasure one of the successful books of last year, "A Daughter of the Pit," written by Margaret Doyle Jackson, who is the wife of the

writer of the present novel. Mrs. Jackson's book published by Houghton, Mifflin & Company, went through a number of editions and received a full meed of praise from the critics of the country generally. Dr. Jackson's book, published by Dillingham, promises to be at least as great success, and will be an almost unique example of conjugal talent for novel writing developing on both sides, long after marriage. This is an interesting melodramatic story with a murder and poisoning case, the poisoning being done by one of the recently discovered synthetic products, whose name is concealed because the legal authorities of the story consider it advisable not to put such a dangerous weapon as this into the hands of the public. As the interesting fact is brought out, that when an alcoholic solution of the drug has dried in spots it may be made to detonate, the mystery is perhaps not so deep for those who are more or less familiar with chemicals. The story is a clever one and will doubtless have many readers.

### THE OUTLOOK IN SANITARY SCIENCE.

In an article in the *Booklover's Magazine* for August, 1903, on the lengthening of human life and the victories of modern medical science, Dr. Joseph Walsh, of Philadelphia, sets forth the promising outlook in sanitary science, especially with which the twentieth century opens. Scientific medicine is only in its infancy. Its progress will prolong more and more markedly the average age of life by removing the diseases that play havoc during childhood and adolescence. Cholera infantum, the terror of mothers during the second summer, has within the year delivered up its cause to a medical student, Duval, of the University of Pennsylvania, working under the direction of Professor Flexner. With the examples of Vienna and Munich before us, we realize the fate of typhoid fever, which proves the pitfall of many an ambitious adult. With typhoid will disappear its most notable sequelæ, gall-stones. Thumbs were turned down twenty years ago on the animal parasitic diseases, such as trichinosis and tapeworms, when the late Dr. Joseph Leidy, of Philadelphia, entered the lists and demonstrated how easily they might be conquered.

When the organisms themselves cannot be directly handled the source of contagion will be learned and the diseases thus avoided. Our now constant enemies, tonsillitis, influenza, and tuberculosis, will find it impossible to progress when people realize the uncleanliness of handkerchiefs and come to the use of paper napkins. Diphtheria and whooping-cough, and, probably other diseases, will have one source of contagion removed when pet dogs and cats are kept away from children or carefully held within doors. Inventions outside the problems of medicine will be by no means without influence. We have every reason to believe from analogy that flies are a frequent medium of transferring contagious diseases. Flies breed practically only in stables and the replacing the horse by the automobile means their extermination. In thus depicting the advance of medical science and predicting its ultimate triumph over disease are we anticipating a millennial condition? No, decidedly not. It is only a picture of the end of our present century when man will accomplish his four score and ten in comparative freedom from the disease hobgoblins of to-day. There are those who may think the prophecy too sanguine. Undoubtedly, however, if the promise of the last few years is fulfilled this much may be conservatively anticipated.

### A COUNTRY PHYSICIAN AND THE OPPORTUNITY.

A writer in the New York *Independent* calls attention to the fact that the Pope's physician, who has proved so capable under the trying circumstances of taking care of a nonogenarian, was originally only a practitioner in one of the country towns on the eastern coast of Italy. When the late Pope's preceding physician died there was not a large number of medical men from whom his successor might be selected. All the Italian medical men who are attached to the Italian universities have taken the oath of allegiance to the Italian government, which is considered to be a usurping government by the popes, and consequently are unavailable for the position. Dr. Lapponi, who was practising in a little town not far from Ancona, happened to have been called as the physician of a cardinal who was staying on the east coast of Italy during one summer for his health. The cardinal was very much taken with Lapponi's ways, and especially with his common sense views with regard to care and nursing, rather than drugs as the mainstay for patients advanced in years.

When Pope Leo was looking around for a successor in the office of papal physician this cardinal was very close to him in certain important matters of state, and was consulted with regard to the choice that should be made. He suggested the name of Lapponi and gave such good accounts of his success in his own case that without more ado Pope Leo selected him as his physician. To the surprise of the country practitioner there came to him one day a messenger from Rome with the formal document appointing him physician to the Pope. It was totally unexpected and came as a complete surprise. For a time Lapponi suspected that some of his medical friends might be playing a practical joke on him, but a little inquiry elicited the fact that the documents had come through perfectly regular channels. Lapponi made his way to Rome and was formally welcomed and installed in his position.

He proved in many ways to be the right man in the right place. Leo XIII had always been delicate, but that very fact had made him extremely careful with regard to his health and had made him very ready to follow the slightest suggestion of his physician. Besides he was a man eminently abstemious and not likely to go to excess in any way, except as regards the amount of work he would insist on doing. This was the one difficulty his physician had to encounter, and no directions, however positive, were sufficient to keep the Pope from overworking at certain times. Only once was there a decided difference of opinion in other matters between the Pope and his physician. Pope Leo had lost several teeth when he was considerably over eighty. One of the Cardinals suggested he might very well replace them by a set of teeth made for the purpose. The Pope announced one day to Lapponi that he was about to have himself fitted with a complete new set of teeth. His physician at once objected, and said that if His Holiness had a new set of teeth he would almost surely be tempted to eat things that would not agree with his old stomach. The Pope saw the wisdom of this, and did not get the teeth.

Many of the old nobility in Rome, who have remained faithful in their adherence to the Pope, became the patients of the new Papal physician. The medical men of Rome generally, however, were very ready to admit that Lapponi had not abused the prestige of his position, nor lowered its professional dignity in any way, and that he had indeed proven himself equal to the opportunity which had been so unexpectedly presented to him.

### MEDICINE IN SHAKESPEARE'S TIME.

In a recent number of the *Westminster Review* Dr. John Knott discusses the medical knowledge of Shakespeare. He says that not many allusions to the anatomy

and surgery of the skeleton are met with in the works of the great dramatist. He quotes two or three such references, however—one of which is of special interest. In the *Winter's Tale*, Autolycus calls out that he fears his "shoulder blade is out." Dr. Bucknill's commentary on this passage is an *ex cathedra* pronouncement that "the shoulder blade cannot be dislocated." On this Dr. Knott makes the interesting observation that "as in so many cases where commentators have undertaken to amend Shakespeare, the great poet is quite in accord with the most advanced knowledge of this subject in the present day, while the critic is absolutely wrong." Dr. Bucknill's mistake he attributes to the fact that in the ordinary text-books of the early portion of the last century dislocations occurring at the joint between the shoulder blade and the collar bone were always spoken of as dislocations of the clavicle, as the projecting extremity of that bone produced the resulting deformity. Of muscles as distinct entities in the human framework Shakespeare appears to have had no knowledge whatever; this is not surprising, as the Italian universities were then the only places in which anatomy was systematically studied. Shakespeare's vague use of the terms "nerve" and "sinew" show that he shared the indefinite ideas of his time. Hazy ideas of the circulation had existed among anatomists and physiologists before Harvey was born; and several passages of Shakespeare seem to Dr. Knott to show that Harvey's discovery, which was published after his death, would not have been a startling novelty to him if he had lived. The most definite expression on the subject he finds in *Coriolanus*, in the famous parable of the belly and the other members of the body. The stomach, after describing itself as the storehouse of the food received into the body, says:

I send it through the rivers of your blood,
Even to the court, the heart, to the seat o' the brain;
And through the cranks and offices of man,
The strongest nerves and small inferior veins
From me receive that natural competency
Whereby they live.

"If," says Dr. Knott, "this passage does not indicate a distribution of the pabulum by the circulating fluid to the various tissues of the body, distinctly foreshadowing the outline of what is known at the present day, I cannot suggest any other interpretation." After citing a number of instances of Shakespeare's references to matters connected with medicine, Dr. Knott justly points out that medical knowledge in the strictest sense did not exist in Shakespeare's day. "But when it comes to description of symptoms which may be observed at the bedside of the sick or dying, and which, the human organism being the same then and now, are familiar to every practising physician, we find them recorded by the dramatist with a vivid accuracy which cannot be surpassed." Dr. Knott's paper is an example of the blending of medical knowledge with literary taste which we are always glad to welcome in the members of our profession. Literature of the right kind enlarges and deepens human sympathy, which is apt to become shriveled and hardened if exposed too exclusively to the dry light of Science.—*British Medical Journal.*

## BOOK REVIEWS.

Studies in the Psychology of Sex. Analysis of the Sexual Impulse; Love and Pain; the Sexual Impulse in Women. By Havelock Ellis. F. A. Davis Company, Philadelphia.

The author is recognized as one of the most able and careful students of the subject of this small volume. He is sound and thoroughly acquainted with an extensive literature that is neither prurient nor obscene

He here presents three studies, parts of which have appeared in other places, all of which are worthy of study by those called on to deal with problems of sex, and what physician is not?

The analysis of the Sadistic and Masochistic phenomena is especially able and thorough.

These books are not for general reading, but they are valuable to the true student.

International Clinics: Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, Neurology, etc. By Leading Members of the Medical Profession Throughout the World. Edited by A. O. J. Kelly, A.M., M.D., Philadelphia. Volume II, Thirteenth Series, 1903. J. B. Lippincott Company, Philadelphia.

This second volume of the International Clinics under its new editor fulfils the promise of its predecessor. There is an excellent symposium on the summer diarrheas of children, which begins with a biological discussion of milk bacteria and intestinal disorders by H. W. Conn, of Wesleyan University. Among the important articles of the volume may be noticed "Practical Notes on the Prophylactic and Curative Treatment of Influenza, Malaria, Erysipelas and Ozena," by J. McFadden Gaston, of Atlanta; "The Rest Treatment, When Indicated and How Conducted," by J Madison Taylor, of Philadelphia; "The Etiology, Prevention and Treatment of a Common Cold," by Alexander Haig, of Edinburgh, Scotland, and the "Causation and Treatment of Sterility in Women," by Dr. J. Riddle Goffe, of New York City.

On Syphonage and Hydraulic Pressure in the Large Intestine with Their Bearing upon the Treatment of Constipation, Appendicitis, etc. By Ralph Winnington Leftwich, M.D., Late Assistant Physician for the East London Children's Hospital. Author of "An Index of Symptoms," etc. William Wood & Co., New York.

Dr. Leftwich has conceived the idea that the large intestine works on the principle of the syphon. The first paragraph of the book is as follows: "Many centuries have passed since the large intestine was described and many thousands of anatomists have examined it closely.' Among them some must surely have marveled that a mechanism so ill-adapted to an erect being could do its work so well. There is a key to the problem, but without the key nothing could well appear more faulty than the design." The key, according to Dr. Leftwich, is the fact that the long arms of the ascending and descending colon act as a syphon. The new theory has some interesting practical features that are well brought out.

## BOOKS RECEIVED.

*The* Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

Text-Book of the Diseases of Women. By Thomas A. Ashley, M.D. 8vo, 661 pages. Illustrated. Williams & Wilkins Company, Baltimore.

Manual of the Diseases of the Eye. By Charles H. May, M.D. Third edition. 12mo, 408 pages. Illustrated. Wm. Wood & Co., New York.
